Abstract

This paper presents a comprehensive set of stylised facts for business cycles in India from 1950 - 2009. We find that the nature of the business cycle has changed dramatically after India’s liberalisation reforms in 1991. In terms of volatility, key macroeconomic variables are less volatile in the post reform period compared to the pre-reform period. However, the volatility of macroeconomic variables in the post-reform period in India is still high and similar to emerging market economies. In contrast, in terms of co-movement and persistence, India looks more similar to advanced economies. Our results are consistent with India’s structural transformation from a pre-dominantly agricultural and planned developing economy to a more market based industrial-income economy. This is the first exercise of this kind to generate a full and robust set of stylised facts for India using both annual and quarterly data.

1 Introduction

This paper describes the changing nature of the Indian business cycle from 1950 - 2009. Our focus is to compare India’s business cycle in the pre 1991 economy, with the post 1991 Indian economy, after the large scale liberalization reforms of 1991. Our main finding is that after the liberalisation of the Indian economy in 1991, in terms of volatility, key macroeconomic variables are less volatile in the post reform period compared to the pre-reform period. However, the volatility of macroeconomic variables in the post-reform period in India is still high and similar to emerging market economies. In contrast, in terms of co-movement and persistence, India looks more similar to advanced economies, and less like emerging market economies.

In recent years, considerable research initiative in the field of international business cycle has focused on documenting stylized features of business cycles and developing dynamic stochastic general equilibrium (DSGE) models to explain them. Traditionally, studies in this area of research have primarily dealt with documenting business cycle features of major developed economies (Kydland and Prescott, 1990; Backus and Kehoe, 1992; Stock and Watson, 1999; King and Rebelo, 1999). Recently, there is a growing interest in understanding the business cycle features of developing and emerging market economies (Agenor et al., 2000; Rand and Tarp, 2002; Male, 2010) and compare them with those of developed economies (Kim et al., 2003; Neumeyer and Perri, 2005; Aguiar and Gopinath, 2007).

This paper presents stylised facts of Indian business cycles from 1950 - 2009. India provides an interesting example as the nature of cycles have changed after India liberalised and moved away from a planned, agricultural and closed economy characterised by controls on capacity creation and high import duties; to a market determined industrializing open economy. Our paper extends the existing literature by investigating the change in the nature of Indian business cycle in response to the change in the policy environment.

In particular, our paper compares the properties of Indian business cycle over two periods: 1950-1991 for the pre-liberalisation period and 1992-2009 for the post-liberalisation period. GDP, private consumption, total gross fixed capital formation, consumer prices, exports, imports, government expenditure and nominal exchange rate are the key variables analysed. The quantitative general equilibrium literature reports strong counter-cyclicality of net exports and highly volatile and counter cyclical interest rates in emerging markets. We also report the business cycle properties of these variables for India, though our results differ. We follow the standard procedure in the
international business cycle literature and decompose the time series into secular and cyclical components. Several methods are available for implementing this type of trend-cycle decomposition. We adopt the commonly used Hodrick-Prescott filter to derive the cyclical components and then check the robustness of our results with the Baxter-King filter. The cyclical components are then used to study the business cycle characteristics of volatility, co-movement and persistence.

The paper’s main contribution is to highlight the difference in the properties of the Indian business cycle stylised facts over the two periods, and suggest reasons for these changes. Our main finding is that after the liberalisation of the Indian economy in 1991, the properties of the Indian business cycle resemble an economy closer in some ways to advanced economies. Specifically, we find that key macroeconomic variables in our dataset are less volatile in the post reform period compared to the pre-reform period. The reduction in volatility resembles that of advanced economies (Kydland and Prescott 1990; Backus and Kehoe 1992; Stock and Watson 1999; King and Rebelo 1999) and other Asian economies (see Kim et al. (2003)) that have experienced structural transformation. However, we find that the level of volatility of macroeconomic variables in the post-reform period is still high and comparable to emerging market economies. In terms of emerging markets, this is consistent with the findings of Male (2010), Neumeyer and Perri (2005), and Alper (2002) that report higher output volatility for developing and emerging market economies. In addition, consumption is more volatile than output in the post-reform period, this is similar to the findings of Kim et al. (2003) that report higher relative consumption volatility for most of the Asian economies in the second period.

In contrast, in terms of co-movement and persistence, the Indian business cycle looks similar to advanced economies. There is an increase in the co-movement of investment with respect to output. Imports have become more pro-cyclical in the post reform period. Government expenditure volatility has fallen. Net exports show a transition from being a-cyclical in the pre-reform period to counter-cyclical in the post reform period. There is higher persistence for all the key macroeconomic variables in the post reform period. The volatility in prices has also decreased and the absolute volatility in the nominal exchange rate has declined. India thus looks more similar to advanced economies, and less like emerging market economies, when we look at the co-movement and persistence of key macroeconomic variables.

The remainder of the paper is structured as follows. Section 2 outlines the main features of emerging economies business cycle with an overview of the
sources of shocks in these economies. Section 3 presents a snapshot of India’s transition. Section 4 outlines the data sources and the variables included in the study. Section 5 details the methodology employed to compute the Indian business cycle stylised facts. Section 6 provides empirical evidence on the changing Indian business cycle stylised facts from pre to post reform period. Section 7 presents results on sensitivity tests. Section 8 concludes. A data appendix lists the sources and definitions of variables used in this study.

2 Stylised Facts from Emerging Economies

As noted in the introduction, one of the main features that distinguishes emerging economies business cycles from advanced economies is their higher volatility. Current account balances, output growth, interest rates, and exchange rate tend to exhibit larger, and more frequent changes (Calderón and Fuentes, 2006). There are other aspects that characterize emerging market economies: consumption is more volatile than output with a relative volatility larger than one; real interest rates are highly volatile and counter-cyclical, and net exports are strongly counter-cyclical (Kim et al., 2003; Neumeyer and Perri, 2005; Aguiar and Gopinath, 2007; Uribe and Yue, 2006).

As a point of reference, we reproduce Table 1 from Aguiar and Gopinath (2007). The analysis covers 13 developed and 13 emerging economies based on a quarterly dataset. The findings in Table 1 are broadly consistent with the findings of other papers on the business cycle stylised facts of developing economies.\footnote{Empirical work on emerging market business cycles has led to quantitative general equilibrium models both in the RBC and DSGE tradition on understanding the key properties of emerging market business cycle fluctuations (Aguiar and Gopinath, 2007; Chakraborty, 2008; Neumeyer and Perri, 2005; Uribe and Yue, 2006; Batini et al., 2010; Gabriel et al., 2010; Garcia-Cicco et al., 2010).}

Table 1 shows that the business cycle characteristics of developed and emerging economies differ on some important dimensions. Emerging economies, on an average have higher output volatility compared with the developed economies. Table 1 shows an average volatility of 1.34 for developed economies and 2.74 for emerging economies. Another important difference is that consumption tends to be more volatile than output in emerging economies. The average relative volatility of consumption is 1.45 for emerging economies and 0.94 for developed economies. Relative investment volatility is comparatively higher for emerging economies at 3.91, compared to 3.41 for developed economies.

A distinguishing feature of emerging economies business cycle is the strong counter-cyclicality of trade balance at the business cycle frequencies. According to Aguiar and Gopinath (2007), this property follows from the nature of shocks governing fluctuations in developed and emerging economies. The productivity processes can be in the form of a transitory shock around the trend growth rate of productivity and a stochastic trend growth rate. In an emerging market setting, a shock to the growth rate implies a boost to current output, but an even larger boost to future output. This implies that consumption responds more than income, reducing savings and generating a current account deficit. If growth shocks dominate transitory income shocks, the economy resembles a typical emerging market with its volatile consumption process and counter-cyclical current account. Conversely, a developed economy characterised by relatively stable growth process will be dominated by standard, transitory productivity shocks. Such a shock will generate an incentive to save that will offset any increase in investment, resulting in limited cyclicality of the current account. However, counter-cyclical net exports is also reported for developed economies by Stock and Watson (1999); Rand and Tarp (2002).
Aguiar and Gopinath (2007) use a standard RBC model to explain the business cycle properties of emerging markets. Because emerging market economies are characterized by frequent changes in economic policy, they assume that shocks to trend growth are the primary source of fluctuations. This implies that the random walk component of the Solow residual is relatively larger. However, Calderón and Fuentes (2006) suggest that because the sources of shocks in Aguiar and Gopinath (2007) remain a black box, it is not clear whether these are being driven by changes in economic reforms, or other market frictions. Indeed, Chari et al. (2007) show that a variety of frictions can be represented in reduced form as Solow residuals. Garcia-Cicco et al. (2010) show that when estimated over a long sample, the RBC model driven by permanent and transitory shocks - a la Aguiar and Gopinath (2007) - does a poor job in explaining observed business cycles in Argentina and Mexico, along a number of dimensions. These findings of Garcia-Cicco et al. (2010) suggest that the RBC model driven by productivity shocks does not provide an adequate explanation of business cycles in emerging economies.

Other papers in the literature, such as Neumeyer and Perri (2005) emphasize the interaction between foreign interest rate shocks and domestic financial frictions that drive business cycle fluctuations in emerging market economies. Firms in their model demand working capital to finance their wage bill making labour demand sensitive to interest rate fluctuations. An increase in the emerging market country’s interest rate leads to a rise in labour costs. Since labour supply is insensitive to interest rate shocks, a lower demand for labour leads to lower levels of employment and output in equilibrium. Uribe and Yue (2006) find that both country interest rates drive output fluctuations in emerging market economies as well as the other way around. Kose et al. (2003) analyse the importance of domestic and external factors as causing cycles. Calvo (1998) argues that the idea of sudden stops are an important determinant of large cycles in emerging markets.

3 India in Transition

A discussion of the sources of aggregate business cycle fluctuations assumes greater relevance for a country like India that has undergone significant transformation since 1950. This transformation has occurred in three areas. While agriculture has fallen as an overall share of the economy, since 1991, India has moved from a planned to a non-planned market oriented economy as well as from a closed to an open economy.
In particular, prior to 1991, positive productivity shocks could not be accommodated and generated inflationary pressures and a worsening of the exchange rate. After the 1991 reforms, the same shocks were permitted to generate growth, making investment and imports go up, with foreign investment flowing in and the exchange rate appreciating. However, the transformation of the Indian economy to a more open economy has been accompanied by high growth, as well as a sharp increase in India’s integration on both trade and financial flows, possibly leading to one source of volatility noted above.

Even though we focus on the changing pattern of the Indian business cycle and as this relates to changes in the policy regime in 1991, some of the key elements of transformation in the Indian economy from 1950 - 2009 are:

1. Reduction in the consumption-output ratio: The first two plots of Figure 1 show the behaviour of the consumption-output ratio and investment output ratio from 1950-2009. The graphs show that while the share of private consumption has declined, there is a gradual and consistent increase in the share of investment in GDP.

5 Ramey and Ramey (1995) however find, that there is a negative correlation between volatility and growth. This would suggest that whether India’s output is more volatile (compared to OECD economies), because it is growing faster, would seem unlikely, unless growth has increased volatility and volatility itself reduces growth subsequently.

6 Jayaram et al. (2009) show that the integration with the global economy has also resulted in greater business cycle synchronisation with advanced economies and with the US.

7 Aguiar and Gopinath (2007) suggest that consumption volatility is high because of permanent productivity shocks, i.e., consumption volatility is driven by shocks to income that are larger or more persistent than they should be. Another source of volatility is when productivity shocks get amplified by frictions as in Aghion et al. (2004). Here, excess output volatility results because of capacity under-utilization. Aghion et al. (2010) show however that there is not much evidence that investment responds more to productivity shocks in economies with less good capital markets. On the other hand, the paper also finds that the fraction of long term investment in total investment is more pro-cyclical in economies with less good capital markets. If long run investment enhances productivity, then the reform story implicit in this paper acquires salience.
Figure 1 The story of India’s transition

In addition, since the mid 1990s, the Indian economy has undergone a significant transformation in many aspects. From a purely monsoon driven economy, fluctuations in the economy are now driven primarily by fluctuations in inventory and investment. The share of investment in GDP has increased from 13% in 1950-51 to 35% in 2009-10. The increase has been particularly prominent since 2004-05.

2. Declining share of agriculture: In the India of old, monsoon performance used to define a good or bad time. Adverse agricultural performance used to throw GDP growth off trend [Shah 2008, Patnaik and]
In the India of present times, monsoon shocks matter less. This is evident in the declining share of agriculture in Indian GDP. The third graph in Figure 1 shows a consistently declining share of agriculture since 1950s. Table 2 shows the changing composition of Indian GDP, the decline in the share of agriculture has been matched with a rise in the share of services.

3. Shift away from state domination: An important dimension of India’s transition is the shift away from state domination towards a market economy. This is visible in the fourth graph of Figure 1. The graph shows that the share of public investment in total investment surged in the 1960s and 1970s. Since then it has been consistently declining.

4. Emergence of a conventional business cycle: The policy set up in India of old times was characterised by controls on capacity creation and barriers to trade. In such a scenario, conventional business cycles characterised by an interplay of inventories and investment did not exist. One prominent source of investment was government investment in the form of plan expenditure, which did not show any cyclical fluctuations. In the present environment with eased controls on capacity creation and dismantling of trade barriers, private sector investment as a share of GDP has shown a significant rise.

The fifth graph in Figure 1 shows the time series of private corporate gross capital formation expressed as a percent to GDP. In recent years we can see the emergence of the behaviour found in the conventional business cycle. In the investment boom of the mid-1990s, private corporate GCF rose from 5% of GDP in 1990-91 to 11% of GDP in 1995-96. This then fell dramatically in the business cycle downturn to 5.39% in 2001-02, and has since recovered to 17.6% in 2007-08. The recent recession has led to its fall to 13.5% in 2009-10.

5. Increased integration with the rest of the world: The India of old was sheltered from external competition through high import duties and other barriers to trade. The capital account was also subject to strict
regulations on inflows and outflows. Since the adoption of liberalisation policy, the restrictions on current and capital account have been eased. This has resulted in India moving away from an autarky situation.

An effective way of measuring the openness is to sum the earnings and payments on the current and capital account and express the sum as a percent to GDP. The last graph in Figure shows the time series of current and capital account flows expressed as a percent to GDP. In the pre-reform period the flows on current and capital account were around 20% of GDP. The conducive policy environment has resulted in both current and capital account flows to GDP ratio rising to around 60% each in 2009.

4 The Dataset

We now undertake a formal analysis of Indian business cycle stylised facts. In India, quarterly data for output and key macroeconomic variables is available only from June 1999. To understand the changing nature of Indian business cycles, we examine annual data. We then check the validity of our results with quarterly data. This is consistent with the literature on stylised facts (King and Rebelo 1999; Stock and Watson 1999; Male 2010), that relies on quarterly data to study business cycle properties of macroeconomic variables. Following King and Rebelo (1999) we choose private consumption and investment as key variables. In addition, we analyze exports, imports, net exports, consumer prices (Consumer Price Index-Industrial Worker (cpi-iw)), government expenditure and the nominal exchange rate. Data on hours worked, real wage rate and total factor productivity is not available for India. We use GDP as a measure of aggregate activity in the economy.

For the annual analysis, we have a sample period covering 1950-2009. To study the transition of the economy, the data is analyzed in two periods: the pre-liberalisation period from 1950-1991 and the post liberalisation period from 1992 to 2009. The primary data source is the National Accounts Statistics of the Ministry of Statistics and Programme Implementation. The data for consumer prices is taken from the Labour Bureau, Ministry of Labour and Employment. The data for government expenditure is taken from the budget documents of the Government of India. GDP, private consumption, gross fixed capital formation, exports and imports are expressed at constant

---

8In most countries the headline inflation number is consumer prices, in India it is wholesale prices. We follow the literature on stylised facts in using consumer prices.
prices with base 2004. Government expenditure is expressed in real terms by deflating it with the GDP deflator. Following Agenor et al. (2000) and Neumeyer and Perri (2005) net exports is divided by real GDP to control for scale effects. We source the data from the Centre for Monitoring Indian Economy (CMIE), who source it from the primary data sources mentioned above. All variables and their sources are described in detail in the Appendix.

For their analysis of investment, King and Rebelo (1999) use only the fixed investment component of gross domestic private investment. The other components of gross domestic private investment are residential and non-residential investment. The volatility of gross domestic private investment in the US is higher than the component of fixed investment as residential investment is highly volatile. We take gross fixed capital formation as a proxy for investment since unlike the US, we do not have data on the categories of gross investment.

The variables analyzed are first log transformed. The cyclical components of these variables are then obtained from the Hodrick-Prescott filter, as is standard in the literature (King and Rebelo, 1999; Agenor et al., 2000; Neumeyer and Perri, 2005). The cyclical components are then used to derive the business cycle properties of the variables in terms of their volatility, co-movement and persistence. For the sensitivity analysis, we test the robustness of our results by using the band-pass filter of Baxter-King (Agenor et al., 2000). As a further check, we also use quarterly data to verify the validity of our results.

5 Statistical Methodology

The business cycles examined in the literature are typically known as growth cycles, extending from the work of Lucas (1977) where the business cycle component of a variable is defined as its deviation from trend.\footnote{Much of the literature following Nelson and Plosser (1991), supports the view that it is impossible to distinguish large stationary auto-regressive roots from unit autoregressive roots, and that there might be non-linear trends. With a near unit root, linear de-trending will lead to spurious cycles. See Stock and Watson (1999).} We follow\footnote{Business cycles dating goes back to the early work by Burns and Mitchell (1946). The classical approach propounded by Burns and Mitchell (1946) defines business cycles as sequences of expansions and contractions in the levels of either total output or employment. In 1990, Kydland and Prescott (1990) established the first set of stylised facts for business cycles in other developed economies, based on their research of US business cycle.}
this standard methodology in deriving the stylised facts for Indian business cycles.

For annual data analysis, the log transformed series is passed through a filter to extract the cyclical (stationary) and trend (non-stationary) component. In case of quarterly data, the variables are adjusted for seasonal fluctuations using the x-12-arima seasonal adjustment program. Once adjusted for seasonality, the series are transformed to log terms and then filtered to extract the cyclical and trend component.

A large literature exists on the choice of the de-trending procedure to extract the business cycle component of the relevant time series (Canova, 1998; Burnside, 1998; Bjornland, 2000). Canova (1998) argues that the application of different de-trending procedures extract different types of information from the data. This results in business cycle properties differing widely across de-trending methods. However, commenting on (Canova, 1998), Burnside (1998) shows through spectral analysis, that the business cycle properties of variables are robust to the choice of the filtering methods if the definition of business cycle fluctuations are uniform across all the de-trending methods.

In choosing the technique to derive the cyclical component, the literature on stylised facts mainly relies on either the Hodrick-Prescott filter (King and Rebelo, 1999; Male, 2010) or the band-pass filter proposed by Baxter and King (Stock and Watson, 1999). We use the Hodrick-Prescott filter (Hodrick and Prescott, 1997) to de-trend the series and then check the robustness of our results with the Baxter-King filter (Baxter and King, 1999).

In essence, the Hodrick-Prescott method involves defining a cyclical output $y^c_t$ as current output $y_t$ less a measure of trend output $y^g_t$ with trend output being a weighted average of past, current and future observations:

$$y^c_t = y_t - y^g_t = y_t - \sum_{j=-J}^{J} a_j y_{t-j}$$

After de-trending the series to obtain the cyclical components, we can then determine the properties of the business cycle. In the subsequent analysis, all references to the variables refer to their cyclical component. The cyclical component of the variable is used to derive the volatility, co-movements and persistence of variables.

Our definition of these terms is standard in the literature. Volatility is a measure of aggregate fluctuations in the variable of interest. It is measured by the standard deviation of the variable. Relative volatility is the ratio
of volatility of the variable of interest and the variable used as a measure of aggregate business cycle activity. A relative volatility of more than one implies that the variable has greater cyclical amplitude than the aggregate business cycle.

Contemporaneous co-movements with output series indicate the cyclicality of key macroeconomic variables. In particular, the degree of co-movement of a variable of interest $y_t$ with the measure of aggregate business cycle $x_t$ is measured by the magnitude of correlation coefficient $\rho(j)$ where $j$ refers to leads and lags [Agenor et al., 2000]. The variable is considered to be pro-cyclical if the contemporaneous coefficient $\rho(0)$ is positive, a-cyclical if the contemporaneous coefficient $\rho(0)$ is zero and counter-cyclical if the contemporaneous coefficient $\rho(0)$ is negative.

Finally, persistence indicates the inertia in business cycles. It also captures the length of observed fluctuations. This is measured by the first order autocorrelation coefficient. A high coefficient implies a persistent, long economic fluctuation. Positive coefficients indicate that high values follow high values, or low values follow low values. Negative coefficients indicate reversals from high to lower values, or vice-versa.

6 Indian Business Cycle Stylised Facts in the Pre and Post Reform Period

Table 3, which constitutes the main finding of this paper shows the changing nature of the Indian business cycle from 1950 - 2009.

The main features can be summarized as follows:

- *Volatility of key macroeconomic variables*: High macroeconomic volatility is considered both a source as well as reflection of underdevelopment [Loayza et al., 2007]. Aggregate GDP has seen a decline in volatility from 2.13 in the pre-reform period to 1.78 in the post-reform period. This is consistent, in particular, with the experience of other major Asian economies [Kim et al., 2003]. This is due to a decline in volatility in the agricultural component of GDP.\(^\text{11}\) The volatility of non-agriculture GDP however has gone up in the post reform period. The volatility of investment has declined from 5.26 in the pre-reform period

\(^{11}\)The volatility of the agricultural GDP has fallen to half from 4.26 in the pre-reform period to 2.56 in the post-reform period due to better agricultural performance.

To 5.10 in the post-reform period. Consumer prices, imports, government expenditure and nominal exchange rate have also become less volatile in the post-reform period. Government expenditure volatility is however still higher than output volatility in the post-reform period. However, the fall in volatility is not common to all the macroeconomic variables that we consider. Private consumption and exports have seen a marginal increase in volatility from 1.82 to 1.87 and 7.14 to 7.71 respectively in the post-reform period.

- *Increased pro-cyclicality of investment with output*: A significant feature of modern capitalist economies is that investment is highly procyclical vis-a-vis the aggregate business cycle. Table 3 reports a significant increase in contemporaneous correlation of investment with output from 0.22 in the pre-reform period to 0.60 in the post reform period.

- *Increased pro-cyclicality of imports with output*: Imports have become pro-cyclical in the post-reform period. The external sector policies in the pre-reform period were based on protectionism and import licensing. This is reflected in a negative correlation of imports with output in the pre-reform period. The policy thinking underwent a major change in post 1991 period. Tariff barriers were reduced and non-tariff barriers were dismantled in the mid 1990s. The demand for raw material imports increased substantially with easing of capacity controls on industries. This resulted in imports fluctuating with changes in aggregate.
business activity. Table 3 shows an increase in the contemporaneous correlation of imports from an insignificant -0.19 in pre-reform period to 0.70 in post-reform period. The pro-cyclical nature of imports is again a feature similar to those for advanced open economies.

- **Counter-cyclical nature of net exports:** Since imports are significantly pro-cyclical and exports are not highly correlated with GDP, on balance this leaves us with a counter-cyclical nature of net exports. Table 3 shows a transition from a-cyclical in net exports to counter-cyclical net exports.

- **Counter-cyclical nature of nominal exchange rate:** The nominal exchange rate has turned counter-cyclical in the post-reform period. From an a-cyclical relation in the pre-reform period, the post-reform period shows that the exchange rate goes up in bad times and moves down in good times. This is indicative of the presence of a flexible exchange rate regime in the post-91 period.

- **Persistence** As mentioned before, persistence indicates the inertia in business cycles. It also captures the length of observed fluctuations. Real GDP exhibits weak persistence in the pre-reform period, although there is higher persistence in pre-reform non-agricultural GDP. In the post-reform period, the persistence of real GDP increases substantially, which provides more leeway for predicting the course of business cycles.

In summary, the above analysis shows that the properties of the Indian business cycle resemble an economy closer in some ways to advanced economies. A careful look at Table 3 shows that though the level of volatility of key macroeconomic variables has declined, it is still high and similar to emerging market economies. For example, the volatility of real GDP declines from 2.13 to 1.78 in the pre to post reform period. These numbers are closer to the volatility statistics reported by Kim et al. (2003) for Asian economies before and after the structural transformation respectively. The volatility numbers are also comparable to those reported by Alper (2002) for Mexico and Turkey but much higher than the numbers reported for the U.S. An interesting finding is that the relative volatility of consumption has gone up in the post-reform period, again similar to the findings reported by Kim et al.

---

13 The paper compares the business cycle stylised facts of seven Asian economies for the period 1960-1984 and 1984-1996. The mean volatility declines from 3.00 in the first sub-period to 2.00 in the second sub-period.
While the absolute volatility of trade variables has marginally declined, the relative volatility is still high. This is consistent with the findings of Kim et al. (2003) who report reduced but still higher relative volatility of trade variables as compared to those of the G-7 countries.

In contrast, the Indian business cycle is similar to the developed economies on co-movement and persistence of macroeconomic variables. Table 3 shows that the contemporaneous correlation of investment with output increases from 0.22 in the pre-reform period to 0.77 in the post-reform period. While the post-reform correlation figure is higher than the number reported by Kim et al. (2003) for Asian economies for their second period, it is similar to the numbers reported by Male (2010) for developed economies. Similarly, the correlation of imports with output increases in the post-reform period. The figure reported in Table 3 is much higher than the corresponding average correlation figures reported by Kim et al. (2003). Another feature on which the Indian business cycle resembles that of an advanced economy is the persistence of macroeconomic variables. As an example, the persistence of output reported in Table 3 is greater than the average persistence figures reported for Asian economies by Kim et al. (2003) and for developing economies by Male (2010).

7 Robustness Checks

In this section we perform robustness checks to test the validity of our results.

7.1 Robustness of Correlation Results

Following (Ambler et al., 2004), we investigate whether our correlation results are mere statistical noise or are robust to procedures for testing the statistically significant difference in correlation. The procedure for testing the statistically significant difference in correlation involves the following steps:

- Let $r_1$ be the correlation between the two variables for the first group with $n_1$ subjects.
- Let $r_2$ be the correlation for the second group with $n_2$ subjects.
- To test $H_0$ of equal correlations we convert $r_1$ and $r_2$ via Fisher’s variance stabilizing transformation $z = 1/2 \cdot \ln[(1 + r)/(1 - r)]$ and then calculate the difference:
Table 4 shows the difference in correlation and the associated p-value. The application of the test shows that the difference in correlation between the pre and post-reform period is statistically significant for investment, imports, net exports and the nominal exchange rate. These are the variables that drive the transition in the economy from the pre to post reform period. As an example, these results imply that the difference in the cyclical relation between, say, investment and output, is statistically significant between the pre and post reform period.

For private consumption, CPI, exports and government expenditure, the test results are not significant. This implies that the nature of correlation of these variables with output does not change between the pre and post reform period.

7.2 Using Quarterly Data

In this section we present the results with quarterly data to check whether the results are consistent with results for the post-reform period in the annual data. The quarterly data for GDP is available from 1999 Q2, hence our quarterly data analysis starts from 1999 Q2. Figure 2 shows the detrended path of the key variables with output proxied by GDP. The cyclical component of the GDP series is placed in each panel of the figure to gauge

\[ z_f = (z_1 - z_2) / \sqrt{1/(n_1 - 3) + 1/(n_2 - 3)} \]

- The difference is approximately standard normal distribution.
- If the absolute value of the difference is greater than 1.96 (assuming 95% confidence interval) then we can reject the null of equal correlations.
the relative volatility and co-movement of each series in question with the reference series.

Business cycle stylised facts for key variables are provided in Table 5.

*Volatility*: Table 5 shows private consumption as more volatile than output. This is similar to the finding for other developing economies. In general, consumption is 40 percent more volatile than income in developing economies. Conversely, in developed economies the ratio is slightly less than one on average (Aguiar and Gopinath, 2007). Table 5 reports the relative volatility of private consumption for India as 1.31.

Prices are also more volatile than output. Again, this is consistent with the findings for developing economies. In Latin American countries, prices are six times more volatile than output (Male, 2010). The relative volatility of price level for India is 1.09.

Exports and Imports exhibit significant volatility. Higher export and import volatility can also be seen for developed economies, though the extent of volatility is lower (Kim *et al.*, 2003). For India, the relative volatility of exports and imports are 7.40 and 7.52 respectively. Net exports are also found to be more volatile than output.

Consistent with the business cycle facts for developing economies, government expenditure is more volatile than output. The relative volatility of government expenditure is 5.53. Thus on volatility, our business cycle features resemble those of developing and emerging market economies.

Co-Movement: Table 5 shows investment as significantly pro-cyclical. The contemporaneous correlation of investment with output is 0.69. The strong correlation between investment and output for India provides evidence for a growing resemblance between India and advanced economies business cycles. This is consistent with the results from annual data.

Table 5 shows imports as pro-cyclical, while exports as mildly pro-cyclical. Again, this feature indicates resemblance between Indian and advanced economies business cycle facts.

For fiscal policy to play a stabilising role in an economy, government expenditure should be counter-cyclical. A significant difference between the annual and quarterly data analysis pertains to the correlation of government expenditure with output. For the annual analysis, the relation is counter-cyclical, though not significant. With the quarterly analysis, which pertains to recent data, we report a significant counter-cyclical relation between government expenditure and output. The correlation coefficient is -0.35. Crucially, this is similar to the findings for developed economies.

Also consistent with the results of the annual post-reform period, nominal exchange rate is found to be counter-cyclical.

Persistence Using quarterly data, Table 5 shows persistent output fluctuations for the Indian business cycle. The magnitude of persistence is comparable to those of developed economies. Male (2010) finds the average persistence for developed economies to be 0.84 and for developing economies to be 0.59. The persistence of output for India is higher than the developing economies average figure. The persistence is even higher at 0.84 if
non-agricultural GDP is taken as the aggregate measure of business cycle activity.\footnote{These results are available from the authors on request.} Price levels are also significantly persistent. Other variables in Table 5 are also found to be significantly persistent (with the exception of government expenditure and real interest rate).

In summary, the results of the quarterly data analysis broadly confirm the findings of the post-reform period using annual data. The findings support that the Indian economy is in a transition phase. While on volatility, the business cycle features resemble those of developing economies, the correlation and persistence results show growing similarity with the advanced economies business cycle.

### 7.3 The Baxter-King Filter

As another sensitivity measure, we check the robustness of our annual results to the choice of the de-trending technique. Following Stock and Watson (1999); Agenor et al. (2000) we use the Baxter-King to derive the business cycle properties of our macroeconomic variables. Baxter-King filter belongs to the category of band-pass filters that extract data corresponding to the chosen frequency components. We are interested in extracting the business cycle components. In line with the NBER definition, the business cycle periodicity is defined as those ranging between 8 to 32 quarters.

Table 6 reports the results with the cyclical components derived from the Baxter-King filter. The results are broadly consistent with those corresponding to the Hodrick-Prescott filter. Output volatility shows a decline in the post-reform period. On correlation, the results are broadly the same. Investment becomes pro-cyclical in the post-reform period. Exports is insignificantly pro-cyclical while the cyclicality of imports is significant. Since exports is acyclical and imports are pro-cyclical, net exports are found to be counter-cyclical. Similar to the findings with the Hodrick-Prescott filter, nominal exchange rate becomes counter-cyclical in the post-reform period, though the level of significance varies.

There are some notable differences in the results related to volatility. This arises due to differences in the properties of the two filters. While the Baxter-King filter belongs to the category of band-pass filters that remove slow moving components and high frequency noise, the Hodrick-Prescott filter is an approximation to a high-pass filter that removes the trend but passes high frequency components in the cyclical part. The Baxter-King filter, however
tends to underestimate the cyclical component. [Rand and Tarp 2002]  

As an example, in contrast to the findings of the Hodrick-Prescott filter, the absolute volatility of private consumption declines in the post-reform period, when the Baxter-King filter is used to de-trend the variables. The statistical testing procedure shows that the difference in correlations is close to the cut-off value of 1.96, even though it is not as strong as with the Hodrick-Prescott filter.

There are also notable differences with respect to persistence compared to the HP filter. Persistence in the pre-reform period for almost all the variables is low. Real GDP, consumption, and exports have negative persistence. In the post reform period, persistence rises, but the variables are less persistent compared to when the HP filter is used to extract cycles. One possible explanation for this emerges from plotting the spectrum of the cyclical component of a few series, extracted by the BK filter. The spectrum of the cyclical component, shows two peaks: one at intermediate frequencies, and the other higher at higher frequencies. Because there is substantial area under the spectrum of the cyclical component at the higher frequency, the BK filter picks up cycles at higher frequencies compared to the HP filter. These leads to lower persistence in the underlying series.  

Table 6 Business cycle statistics for the Indian economy using annual data: Pre and post reform period (with Baxter-King filter)
We also check the robustness of our results to a change in the sample period. To maintain uniformity in sample size we redefine the pre-reform period as starting from 1971. Our key results do not change with a change in the sample size.\footnote{The results are available from authors on request.}

8 Conclusion

Documenting business cycle stylised facts forms the foundation of quantitative general equilibrium models either in the RBC or DSGE tradition. Such a study assumes greater relevance in the context of an economy like India which has undergone significant transformation since 1991. The industrial sector has been freed from capacity controls, import duties have been reduced and a reasonably conducive environment towards the global economy has evolved over the last few years. The novel aspect of this paper is to present a comprehensive set of stylized facts governing an economy in transition. We locate facts about Indian business cycles in the context of other industrial economies, as well as other emerging and developing countries.

Our main finding is that after the liberalisation of the Indian economy in 1991, in terms of volatility, key macroeconomic variables are less volatile in the post reform period compared to the pre-reform period. However, the volatility of macroeconomic variables in the post-reform period in India is still high and similar to emerging market economies. In contrast, in terms of co-movement and persistence, India looks more similar to advanced economies, and less like emerging market economies.

Future work can use the findings of this paper to assess the extent to which DSGE models, starting with the simplest RBC model through to New-Keynesian models with labour markets and financial frictions introduced in stages, can explain business cycle fluctuations in India. Both closed and open economy models can be examined. Comparisons with a representative developed economy, say the US, can then be made. Proceeding in this way, one will be able to assess the relative importance of various frictions in driving aggregate fluctuations in India. Another avenue for future work relates to \cite{Lucas1987}, which pointed out that the welfare gains from eliminating business cycle fluctuations in the standard RBC model are small, and dwarfed by the gains from increased growth. While adding New Keynesian frictions significantly increases the gains from stabilization policy, they still remain
small compared to the welfare gains from increased growth. However, there is relatively little work introducing long-run growth into DSGE models, and exploring the relationship between volatility and endogenous growth. This takes particular importance for India which has moved to a higher growth path in recent years, with the attendant decline in macroeconomic volatility, as documented in this paper.
