Abstract

We consider deterministic dominant strategy implementation in multidimensional dichotomous domains in private values and quasi-linear utility setting. In such multidimensional domains, an agent’s type is characterized by a single number, the value of the agent, and a non-empty subset of acceptable alternatives. Each acceptable alternative gives the agent utility equal to his value and other alternatives give him zero utility. We show that generation monotonicity is necessary and sufficient for implementability in any dichotomous domain. If such a domain satisfies a richness condition, then a weaker version of generation monotonicity, which we call 2-generation monotonicity (equivalent to 3-cycle monotonicity), is necessary and sufficient for implementation. We use this result to derive the optimal mechanism in a one-sided matching problem with agents having dichotomous types.

1 Introduction

We study multidimensional mechanism design in private value and quasi-linear environments, e.g. auction domains, matching problems with transfers, choosing a public good among multiple public goods with transfers etc. We restrict attention to deterministic implementation in dominant strategies. Our focus is on domains where agents have dichotomous preferences over alternatives. We give a complete characterization of implementable allocation rules when every agent has a dichotomous type. A dichotomous type \( t_i \) of any agent \( i \) is characterized by a positive real number \( v(t_i) \), which we call the value of the agent at this type, and a non-empty subset of alternatives \( A(t_i) \), which we call the acceptable alternatives. The interpretation is that an agent of dichotomous type \( t_i \) gets (the same) utility \( v(t_i) \) from each alternative in his acceptable set \( A(t_i) \), but gets zero utility on any alternative that is not acceptable. Note that both \( v(t_i) \) and \( A(t_i) \) are private information of the agent. This makes such type spaces multidimensional.

We call a type space a dichotomous domain if every type belonging to it is a dichotomous type. We characterize the set of implementable allocation rules in dichotomous domains using a condition called generation monotonicity. Generation monotonicity is a new (non-trivial) simplification of the cycle monotonicity condition of Rochet (1987) in dichotomous domains. Our most striking result comes in a particular class of dichotomous domains. We show that for a large class of dichotomous domains, which we refer to as rich dichotomous domains, a significantly weaker condition than generation monotonicity characterizes implementability. We refer to this weaker condition as 2-generation monotonicity, and show it to be equivalent to 3-cycle monotonicity. 3-cycle monotonicity is significantly weaker than cycle monotonicity but stronger than 2-cycle monotonicity, a condition used to characterize implementability in convex domains (Bikhchandani et al., 2006; Saks and Yu, 2005; Ashlagi et al., 2010). A dichotomous domain is not convex, but still multidimensional. While most of the earlier results found domains where 2-cycle monotonicity is necessary and sufficient for implementability, to our knowledge, this paper is the first to identify multidimensional domains where we see \( K \)-cycle monotonicity (\( K \neq 2 \)) is necessary and sufficient for implementation. We demonstrate usefulness of our characterizations by deriving a revenue maximizing mechanism for the one-sided matching problem where agents having dichotomous preferences over alternatives.

Though dichotomous types seem like a restrictive preference over alternatives, it is natural in many settings. Such preferences have been studied in social choice theory and matching theory in models without monetary transfers - Bogomolnaia and Moulin (2004) and Roth et al. (2005) study it in the context of matching; Bogomolnaia et al. (2005) study it in a collective choice problem; and Vorsatz (2007, 2008) study it in the context of a voting model. Allowing for transfers in some of these models is very natural. Dichotomous domains were first studied with monetary transfers and quasi-linear utility in Babaioff et al. (2005). We discuss two broad settings with transfers where it is plausible to assume that agents have
dichotomous types.

**Collective Choice.** In collective choice problems, agents want to collectively choose an alternative - e.g., joint hiring of a staff by several departments in a university, joint installation of a software for employees in an organization, choosing a communication or transportation network to build for joint use. In each of these problems, it is plausible to think that agents have dichotomous preferences over alternatives - in the staff hiring example, a department gets a value from a staff if and only if he has the skills required by the department; in the software installation problem, an employee gets a value from a software if and only if it is compatible with his laptop; in the network selection problem, if each agent uses the network for sending data from a source node to a destination node, then he gets a value from a network if and only if it connects his source and destination nodes.

**Private Good Allocation.** In private good allocation problems, each agent receives a different alternative and there is usually some feasibility constraint linking the allocations of all the agents. For example, in scheduling problems, each agent has a task (a journey) which can be completed by a machine (airline). The tasks (journeys) of different agents need to be assigned to different time periods because the machine (airline) has capacity constraint in each time period. But an agent may not be available in some time periods, and he gets a value if and only if the task (journey) is assigned to a time period when he is available. Related to this example is the general model of matching with transfers in dichotomous domains - for example, in matching firms to job candidates, a firm may get a value from a candidate if and only if the candidate has the required skills; in matching students to schools, a student may get a value from a school if and only if the language or curriculum of teaching is compatible with the student. The single-minded combinatorial auctions domain (Lehmann et al., 2002) is another example of a dichotomous domain.

Our general characterization using generation monotonicity applies to all these domains. Our specific characterization using 2-generation monotonicity applies to all the above domains except the single-minded combinatorial auction domain.

1.1 Past Literature and Our Results

The study of implementable allocation rules in quasi-linear utility settings with private values began in the seminal paper of Myerson (1981), where he studied Bayes-Nash randomized implementation for the one-dimensional model of the single object auction. For deterministic allocation rules and dominant strategy implementation, Myerson’s result can be easily adapted as follows. He defined the notion of monotone allocation rules, which states that given the type profile of other agents, if an agent gets the object at a type, then he must get the object at a type with higher value. Myerson showed that an allocation rule is implementable if and only if it is monotone in this sense - see extensions of this result for various other one-dimensional problems in Archer and Tardos (2001); Archer et al. (2003);
Goldberg and Hartline (2005); Aggarwal and Hartline (2006); Dhangwatnotai et al. (2008).

For a general multidimensional type space model, Rochet (1987) showed that implementability is equivalent to cycle monotonicity, which requires that for every agent and for every type profile of other agents, certain type graph should have no cycles of negative length.

While cycle monotonicity characterization is very general, it is not an easy condition to verify or interpret - see extensions and different interpretations in Rahman (2011) and Kos and Messner (2011). Researchers have since tried to identify domains where a simpler condition than cycle monotonicity is necessary and sufficient for (deterministic) implementability. Bikhchandani et al. (2006) show that 2-cycle monotonicity, which requires cycles having two nodes in the type graph to have non-negative length, is necessary and sufficient for implementability in a variety of convex domains, including the unrestricted domain and some auction domains. Saks and Yu (2005) generalize this result to show that 2-cycle monotonicity is necessary and sufficient for implementability if the type space of every agent is a convex subset of $\mathbb{R}^{|\mathcal{A}|}$, where $\mathcal{A}$ is the set of alternatives. Ashlagi et al. (2010) show that 2-cycle monotonicity is necessary and sufficient for implementability if the closure of type space of every agent is a convex subset of $\mathbb{R}^{|\mathcal{A}|}$. Vohra (2011) has an excellent survey of these results. Note that the 2-cycle monotonicity condition is equivalent to Myerson’s monotonicity condition in the single object auction model. Our characterization of implementability in rich dichotomous domains uses 2-generation monotonicity, which is equivalent to 3-cycle monotonicity. Since 3-cycle monotonicity is slightly stronger than 2-cycle monotonicity, our result helps further delineate the boundaries of multidimensional domains which permit a characterization that is significantly simpler than Rochet’s cycle monotonicity.

This paper is not the first paper to study implementation in dichotomous domains. Lehmann et al. (2002) consider the specific dichotomous domain of single-minded combinatorial auctions. Under an additional assumption on allocation rules, Lehmann et al. (2002) show that 2-cycle monotonicity characterizes implementability in these domains. Our results are more general than this in the sense that we characterize implementability in arbitrary dichotomous domains. Further, our main characterization in rich dichotomous domain does

---

1This interpretation of cycle monotonicity is due to Gui et al. (2004); Heydenreich et al. (2009). The cycle monotonicity characterization of implementability is related to the characterization of subgradients of convex functions using cycle monotonicity by Rockafellar (1970).

2Vohra (2011) and Heydenreich et al. (2009) discuss an alternate graph theoretic interpretation of cycle monotonicity using allocation graphs. Cuff et al. (2011) have shown that if the type space is a full-dimensional convex product space, then implementability is equivalent to every 2-cycle in the allocation graph having zero length. Since allocation graph is a more complicated concept than the type graph, we do not discuss it in detail in this paper.

3There are many papers which characterize different extensions of implementability in convex domains using 2-cycle monotonicity and additional technical conditions - for Bayes-Nash implementation, see Jehiel et al. (1999) and Muller et al. (2007); for randomized implementation, see Archer and Kleinberg (2008); for implementation with general value functions, see Berger et al. (2010) and Carbajal and Ely (2011).
not apply to single minded auction domains since this domain is not rich in our sense.

A paper closely related to our work is Babaioff et al. (2005). Like us, they consider deterministic implementation in dichotomous domains with monetary transfers. The main difference between their characterization and our characterization is that theirs is a characterization of “mechanisms” (allocation rules and payments), while ours is a characterization of “allocation rules” only. Their characterization says that a mechanism is truthful if and only if the corresponding allocation rule is value monotone, encourages winning, ensures minimal payments, and the payments are by critical values ⁴. We view that our direct characterizations of implementable allocation rules are simpler to state and very different in spirit from the result in Babaioff et al. (2005).

Importantly, our general characterization has many nice implications on specific dichotomous domains, but the characterization in Babaioff et al. (2005) is silent in such domains. Our general characterization using generation monotonicity identifies many specific dichotomous domains where weaker versions of cycle monotonicity is necessary and sufficient for implementability. In rich dichotomous domains, where 2-generation monotonicity characterizes implementability, it implies a cutoff based characterization of implementable allocation rules. This cutoff based characterization extends the cut-off based characterization of Myerson (1981) for single object auction, which states that for every agent and for every type profile of other agents, there is a cutoff value above which this agent gets the object and below which he does not get the object - see also Archer and Tardos (2001) for a generalization of this cutoff based characterization to general one-dimensional models. Our cutoff based characterization for the rich dichotomous domains is more involved.

We hope that such simple characterizations will lead to identifying optimal mechanisms, mechanisms with fairness properties, and (almost) budget-balanced mechanisms in our model. Further, efficiency is usually computationally difficult in many dichotomous domains - for example in single-minded combinatorial auction domains (Blumrosen and Nisan, 2007). So, characterizing the entire class of implementable allocation rules will help us identify computationally tractable but approximately efficient implementable allocation rules.

We demonstrate the usefulness of our results by deriving the optimal mechanism for a particular setting. We consider the one-sided matching problem with agents having dichotomous preferences. In this problem, a set of objects need to be assigned to a set of agents, where each agent can be assigned at most one object. Each agent finds only a subset of the objects acceptable and derives a value if any of these objects are assigned to him. Such a domain easily satisfies the assumptions of a rich dichotomous domain. Amongst the class of dominant strategy incentive compatible and individually rational mechanisms, we identify a mechanism which results in maximum expected revenue for the designer in this problem. Our optimal mechanism extends the optimal auction for the single object case in Myerson (1981).

Our derivation of optimal mechanism for the one-sided matching problem with dichoto-

---

⁴For a precise definitions of these terms, we refer the reader to Babaioff et al. (2005).
mous preferences is a contribution to the optimal multidimensional mechanism design literature. The multidimensional optimal mechanism design problem is believed to be a hard problem. There is a long literature to it after Myerson’s seminal work on the single object auction - see Rochet and Stole (2003) for a survey. This literature usually considers Bayes-Nash randomized implementation. The usual approach in this literature is to consider specific multidimensional domains (sometimes with relaxed incentive constraints), and then extend Myerson’s methodology to such settings - see Armstrong (1996), Blackorby and Szalay (2007), Iyengar and Kumar (2008), Pai and Vohra (2008), Manelli and Vincent (2007). Our optimal mechanism design looks at a different multidimensional domain with deterministic dominant strategy implementation.

2 The Single Agent Model

We consider a single agent model now. Later, we will show how we can extend our results to \( n \) agents. The interpretation of the single agent model is that the type profile of other agents is fixed, and we are looking at the image of an allocation rule where this agent’s type is changing.

The single agent will be denoted by \( i \). There is a finite set of alternatives \( A \). The type of agent \( i \) is a vector in \( \mathbb{R}^{|A|} \). We will denote the type of agent \( i \) as \( t_i \), and the value of any alternative \( a \in A \) at type \( t_i \) as \( t_i(a) \). The set of all possible types of agent \( i \) will be denoted as \( D_i \), and will be referred to as the domain. Agent \( i \) has quasi-linear utility functions, i.e., if he pays a monetary transfer of \( p_i \) and the alternative he receives is \( a \in A \), then his net utility is given by \( t_i(a) - p_i \). We also assume private values - so, when we consider the model with \( n \) agents, the net utility of every agent will be completely determined by his own type and his own monetary transfers.

An allocation rule \( f \) is a mapping \( f : D_i \rightarrow A \). A payment function of agent \( i \) is a mapping \( p_i : D_i \rightarrow \mathbb{R} \).

**Definition 1** An allocation rule \( f \) is **implementable** (in dominant strategies) if there exists a payment function \( p_i \) such that for every \( s_i, t_i \in D_i \),

\[
s_i(f(s_i)) - p_i(s_i) \geq s_i(f(t_i)) - p_i(t_i).
\]

In such a case, we say that \( p_i \) implements \( f \).

We discuss a familiar notion of monotonicity for the allocation rules, and its relation to implementability.

**Definition 2** An allocation rule \( f \) is **\( K \)-cycle monotone**, where \( K \geq 2 \) is a positive integer, if for every finite sequence of types \((t_i^1, t_i^2, \ldots, t_i^k)\) with \( k \leq K \), we have

\[
\sum_{j=1}^{k} [t_i^j(f(t_i^j)) - t_i^j(f(t_i^{j-1}))] \geq 0,
\] (1)
where \( t_i^0 \equiv t_i^k \). An allocation rule \( f \) is cyclically monotone if it is \( K \)-cycle monotone for all positive integers \( K \geq 2 \).

**Remark.** If an allocation rule \( f \) is \((K+1)\)-cycle monotone, then it is also \( K \)-cycle monotone.

In a seminal work, Rochet (1987) showed that an allocation rule is implementable if and only if it is cyclically monotone - also see Rockafellar (1970). The explicit graph theoretic interpretation is due to Gui et al. (2004), where they associate a type graph with every domain \( D_i \), every set of alternatives \( A \), and every allocation rule \( f : D_i \to A \). This type graph contains the set of types as the set of nodes, and is a complete graph (i.e., a directed edge exists from every node to every other node). The length of the edge from node \( s_i \) to \( t_i \) is

\[
\ell(s_i, t_i) := t_i(f(t_i)) - t_i(f(s_i)).
\]

Then, it is easy to notice that Inequality (1) is requiring the length of the cycle \((t_i^1, \ldots, t_i^k, t_i^1)\) to be non-negative.

Though mathematically elegant, this characterization of implementability involves verifying the length of cycles involving arbitrary number of nodes. When the set of alternatives is finite, as is assumed here, one only needs to verify cycles involving no more than \(|A|\) nodes.

**Lemma 1** An allocation rule \( f \) is implementable if and only if it is \(|A|\)-cycle monotone, where \( A \) is a finite set of alternatives.

**Proof:** The proof is in the appendix. \( \square \)

The most general result in the literature, due to Ashlagi et al. (2010), shows that if the closure of a domain is convex, then 2-cycle monotonicity is sufficient for implementation. This is a significant improvement over Lemma 1.

### 3 Implementation in Dichotomous Domains

We now introduce the domain we study in this paper. We call this domain the dichotomous domain.

**Definition 3** A type \( t_i \in \mathbb{R}^{|A|} \) is called a dichotomous type if there exists a positive real number \( v(t_i) \in \mathbb{R}_{++} \) and a non-empty subset of alternatives \( A(t_i) \subseteq A \) such that \( t_i(a) = v(t_i) \) if \( a \in A(t_i) \) and \( t_i(a) = 0 \) if \( a \notin A(t_i) \).

The alternatives in \( A(t_i) \) are called acceptable alternatives of agent \( i \) at \( t_i \) and the positive real number \( v(t_i) \) is called the value of agent \( i \) at \( t_i \). The set \( A(t_i) \) will be referred to as the acceptable set of agent \( i \) at \( t_i \).
We will refer to the tuple of acceptable set and value as the type of the agent. A domain $D_i \subseteq \mathbb{R}^{|A|}$ is called a dichotomous domain if every $t_i \in D_i$ is a dichotomous type. For simplicity, we will sometimes write the dichotomous type $t_i$ as $(v(t_i), A(t_i))$.

Note that there may be restrictions in a dichotomous domain. For example, a particular alternative in $A$ may never be acceptable to the agent - such an alternative always has value zero, and will be referred to as a worthless alternative. For example, in the single-minded combinatorial auction setting, one alternative is to not give any object to the agent. Such an alternative always gives zero value to the agent, and is worthless.

Another restriction can be that if a particular alternative is in the acceptable set, then some other alternative also has to be in the acceptable set. Later, we will give specific domains where such restrictions are natural. However, our general result is not influenced by any such restrictions.

The dichotomous domain is not convex as the following example illustrates.

**Example 1** Let $A = \{a, b, c\}$. Consider a type where the acceptable set is $\{a, b\}$ and value is 2: $t_i = (2, 2, 0)$, and another type where the acceptable set is $\{a, c\}$ and value is 3: $s_i = (3, 0, 3)$. Now, $s_i + t_i = (2.5, 1, 1.5)$, and this is not a dichotomous type.

As a result, the earlier results in the literature on 2-cycle monotonicity being equivalent to implementability does not apply in dichotomous domains.

### 3.1 Generation Monotonicity

We examine the implication of implementability in dichotomous domains. Unless stated otherwise, $D_i$ is a dichotomous domain in this section. The outcome of an allocation rule at a dichotomous type is easy to describe - an agent either gets an alternative in his acceptable set or gets something outside his acceptable set. For every alternative $a \in A$ and for every dichotomous type $t_i$, we define the indicator function $\delta(a, t_i) \in \{0, 1\}$, where $\delta(a, t_i) = 1$ implies that $a \in A(t_i)$ and $\delta(a, t_i) = 0$ implies that $a \notin A(t_i)$. Note that in the type graph of a dichotomous domain, the length of edge from type $s_i$ to $t_i$ can be written as

$$\ell(s_i, t_i) = t_i(f(t_i)) - t_i(f(s_i)) = v(t_i)[\delta(f(t_i), t_i) - \delta(f(s_i), t_i)].$$

We now describe a new monotonicity property in dichotomous domains, and show it to be equivalent to implementability. For this, we will need some notation. Given an allocation rule $f$, a type $t_i$ is satisfied by $s_i$ if $\delta(f(s_i), t_i) = 1$. If $\delta(f(t_i), t_i) = 1$, we say that $t_i$ is satisfied (by itself). If $t_i$ is not satisfied, then we say it is unsatisfied.

We will first define the notion of generations of unsatisfied types. For an allocation rule $f$, define the first generation types of an unsatisfied type $t_i \in D_i$ as

$$G_1^f(t_i) = \{s_i \in D_i : \delta(f(s_i), t_i) = 1\}.$$
So, $G_i^f(t_i)$ contains all the types which satisfy $t_i$ - of course, this will not contain $t_i$ since we consider generations of unsatisfied types only. Also, $G_i^f(t_i)$ may be empty.

Having defined the $k$-th generation types of the unsatisfied type $t_i$, we define the $(k+1)$-st generation types of $t_i$ as follows

$$G_{k+1}^f(t_i) = \{ s_i \in D_i \setminus \bigcup_{j=1}^k G_j^f(t_i) : \delta(f(s_i), \bar{t}_i) = 1 \text{ for some } \bar{t}_i \in G_k^f(t_i) \}.$$ 

So, $G_{k+1}^f(t_i)$ contains all the types which satisfy a $k$-th generation type of $t_i$. Note that for every unsatisfied type $t_i$ and every other type $s_i$, either $s_i$ is not in any generation of $t_i$ or $s_i$ belongs to a unique generation of $t_i$. It is possible that for an unsatisfied type $t_i \in D_i$, $G_k^f(t_i) = \emptyset$ for some $k$. Further, if $t_i$ is unsatisfied and $s_i \in G_k^f(t_i)$ for some generation $k$, then there is no restriction that $s_i$ itself is satisfied or not - we will show later that implementability requires $s_i$ to be satisfied.

We give an example to clarify the concept of generations.

**Example 2** Let $A = \{a, b, c\}$. Suppose $t_i$ is a dichotomous type with $v(t_i) = 2$ and $A(t_i) = \{a\}$. Consider an allocation rule $f$ such that $f(t_i) = b$. Hence, $t_i$ is not satisfied. Now, consider a type $\hat{t}_i$ with $v(\hat{t}_i) = 3$ and $A(\hat{t}_i) = \{a, b\}$, and let $f(\hat{t}_i) = a$. Hence, $f(\hat{t}_i) \in A(t_i)$, and this implies that $\hat{t}_i \in G_1^f(t_i)$. Now, consider another type $\bar{t}_i$ such that $v(\bar{t}_i) = 1$ and $A(\bar{t}_i) = \{b\}$, and let $f(\bar{t}_i) = b$. Then, $\bar{t}_i$ satisfies $\hat{t}_i$ but it does not satisfy $t_i$. Since $\bar{t}_i$ satisfies $t_i$, we have $\bar{t}_i \in G_2^f(t_i)$.

We show that the number of generations of an unsatisfied type for any allocation rule is finite.

**Lemma 2** Suppose $f : D_i \rightarrow A$ is an allocation rule. For all $t_i \in D_i$ such that $f(t_i) \notin A(t_i)$, if $G_k^f(t_i) \neq \emptyset$, then $k \leq |A|$.

**Proof:** Fix any $f : D_i \rightarrow A$, and consider $t_i \in D_i$ such that $f(t_i) \notin A(t_i)$. Suppose $G_k^f(t_i) \neq \emptyset$, and assume for contradiction $k > |A|$. Then for each positive integer $j \leq \gamma^f(t_i)$, we pick some $t_i^j \in G_j^f(t_i)$. Now, consider the set of types $\{t_i^1, \ldots, t_i^k\}$. Since $|A| < k$, there must exist at least two types, say $t_i^j$ and $t_i^{j'}$ with $j, j' \in \{1, \ldots, k\}$ such that $f(t_i^j) = f(t_i^{j'})$. Then it must be that $t_i^j$ and $t_i^{j'}$ belong to the same generation of $t_i$. This is a contradiction.

For an allocation rule $f$, define the generation number of an unsatisfied type $t_i$ in $f$ as the largest positive integer $\gamma^f(t_i)$ such that $G_{\gamma^f(t_i)}^f(t_i) \neq \emptyset$. By Lemma 2, it is well defined. We now define another monotonicity property using generations of types, and show its connection to cycle monotonicity.

**Definition 4** An allocation rule $f$ is $K$-generation monotone, where $K$ is a positive integer, if for every unsatisfied type $t_i \in D_i$ and for every positive integer $k \leq K$, the following holds for all $s_i \in G_k^f(t_i)$,
1. Generation Self Satisfaction (GSS). $s_i$ is satisfied,

2. Monotonicity (MON). $v(s_i) \geq v(t_i)$.

An allocation rule $f$ is **generation monotone** if it is $K$-generation monotone for all positive integers $K$.

We strengthen the notion of generation monotonicity below.

**Definition 5** An allocation rule $f$ is strong $K$-generation monotone, where $K$ is a positive integer, if it is $K$-generation monotone and for every unsatisfied type $t_i \in D_i$ and for every positive integer $k \leq K$, the following holds for all $s_i \in G^f_k(t_i)$,

1. **No Rebirth (NR).** $t_i$ does not satisfy $s_i$.

An allocation rule $f$ is **strong generation monotone** if it is strong $K$-generation monotone for all positive integers $K$.

Strong generation monotonicity and generation monotonicity are related in an obvious way.

**Lemma 3** Suppose $f$ is $(K + 1)$-generation monotone, then it is strong $K$-generation monotone.

**Proof:** Suppose $f$ is $(K + 1)$-generation monotone. Assume for contradiction that $f$ is not strong $K$-generation monotone. Then, for some $t_i$ such that $f(t_i) \notin A(t_i)$ and for some $s_i \in G^f_k(t_i)$, where $k \leq K$, we have that $t_i$ satisfies $s_i$ (violation of NR). Then, $t_i \in G^f_{k+1}(t_i)$. Since $f$ is $(K + 1)$-generation monotone, $t_i$ satisfies itself (GSS). This is a contradiction. ■

Lemmas 2 and 3 immediately establish the following corollary.

**Corollary 1** An allocation rule is strong generation monotone if and only if it is generation monotone.

To understand why generation monotonicity may be linked to implementability (cycle monotonicity), consider 2-cycle monotonicity. Consider two types $t_i$ and $s_i$. The length of the 2-cycle between $s_i$ and $t_i$ is

$$v(t_i)[\delta(f(t_i), t_i) - \delta(f(s_i), t_i)] + v(s_i)[\delta(f(s_i), s_i) - \delta(f(t_i), s_i)].$$

For this cycle to have non-negative length, we need to ensure that when one of the edges has negative length, the other edge must have sufficiently large positive length. Suppose the edge length $\ell(s_i, t_i) < 0$. Then, it must be that $\delta(f(t_i), t_i) = 0$ and $\delta(f(s_i), t_i) = 1$, i.e., $s_i \in G^f_1(t_i)$. The length of this edge is $-v(t_i)$. For the 2-cycle to have non-negative length, we must have $\delta(f(s_i), s_i) = 1$ (GSS), $\delta(f(t_i), s_i) = 0$ (NR), and $v(s_i) \geq v(t_i)$ (MON). This intuition carries forward to higher generations. The following proposition establishes the exact connection between generation monotonicity and cycle monotonicity.
**Proposition 1** For any positive integer $K \geq 2$, an allocation rule is $K$-cycle monotone if and only if it is strong $(K-1)$-generation monotone.

**Proof:** The long proof is in the Appendix. ■

We will now give a characterization of implementable allocation rules using generation monotonicity. For this, we define certain notions. The **generation number** of an allocation rule $f : D_i \rightarrow A$ is a positive number defined as follows. If every $t_i \in D_i$ is satisfied or every unsatisfied $t_i \in D_i$ is not satisfied by any other type (i.e., $G^i_k(t_i) = \emptyset$ for all $t_i$), then we let $\gamma^f = 1$. Else,

$$\gamma^f = \max_{t_i \in D_i : f(t_i) \notin A(t_i)} \gamma^f(t_i).$$

By Lemma 2, the value of $\gamma^f \leq |A|$. We are now ready to state our main characterization.

**Theorem 1** Suppose $f : D_i \rightarrow A$ is an allocation rule with generation number $\gamma^f$. Then, the following statements are equivalent.

1. $f$ is implementable.
2. $f$ is $(\gamma^f + 1)$-cycle monotone.
3. $f$ is $\gamma^f$-generation monotone.

**Proof:** (1) $\Rightarrow$ (2) follows from the fact that implementability implies cycle monotonicity. For (2) $\Rightarrow$ (3), note that if $f$ is $(\gamma^f + 1)$-cycle monotone, by Proposition 1, it is strong $\gamma^f$-generation monotone, and hence, $\gamma^f$-generation monotone. Finally, for (3) $\Rightarrow$ (1), suppose $f$ is $\gamma^f$-generation monotone. Then, by definition of $\gamma^f$, $f$ is generation monotone (this follows from the observation that for any positive integer $k > \gamma^f$, and for any $t_i$ such that $f(t_i) \notin A(t_i)$, we have $G^i_k(t_i) = \emptyset$). In that case, by Lemma 3, $f$ is strong generation monotone. By Proposition 1, $f$ satisfies cycle monotonicity. Hence, $f$ is implementable. ■

Note that the characterization in Theorem 1 holds in any dichotomous domain. In Appendix 2, we identify specific domains where we can find the generation number, and using Theorem 1, we get immediate characterizations in these domains.

**4 Rich Dichotomous Domain**

We now move beyond the general characterization in Theorem 1. We will impose an additional assumption on the domain, and use Theorem 1 to get a simpler characterization of implementability in these domains. A dichotomous domain may have some restrictions. For example, consider the single-minded combinatorial auction domain in Lehmann et al. (2002). To remind, an auctioneer is selling a set of $m$ objects, and the bidder is interested
only in a subset of objects, called his favorite bundle. The set of alternatives in this problem is the set of all subsets of objects. However, if a single-minded bidder has a particular subset of objects \( S \) in his acceptable set, then he must have every superset of \( S \) in his acceptable set. This is a particular restriction on this dichotomous domain.

In this section, we impose a richness condition on the dichotomous domains. Our richness condition rules out some restrictions.

**Definition 6** A dichotomous domain \( D_i \) is **rich** if

(a) the set of possible values of a dichotomous type is an interval \( V = (0, \beta) \), where \( \beta \in \mathbb{R}_{++} \cup \{\infty\} \). \(^5\)

(b) for every alternative \( a \in A \) which is not worthless \(^6\) and every possible value \( x \in V \), there is a dichotomous type \( t_i \) such that \( v(t_i) = x \) and \( A(t_i) = \{a\} \).

Condition (a) is plausible in almost all dichotomous domains. However, condition (b) may not be satisfied in some domains. In particular, it is clearly violated in the single-minded combinatorial auction domain. There are many interesting domains where condition (b) holds. For example, it holds in all the collective choice problems we discussed in Section 1. It also holds in some private good allocation problems that we discussed in Section 1 - e.g., in the scheduling problem and in the matching problem. Thus, it covers a wide variety of dichotomous domains.

The main result of this section gives a characterization of implementable allocation rules in rich dichotomous domains.

**Theorem 2** For any allocation rule \( f : D_i \to A \), where \( D_i \) is a rich dichotomous domain, the following statements are equivalent.

1. \( f \) is implementable.
2. \( f \) is 3-cycle monotone.
3. \( f \) is 2-generation monotone.

**Remark.** Theorem 2 is useful since 2-generation monotonicity is a significantly weaker condition than the generation monotonicity condition in Theorem 1. Further, we use this to derive a “cutoff-based” characterization, which is easier to interpret, in Section 4.2.

**Remark.** In contrast to convex domains, where 2-cycle monotonicity is known to be necessary and sufficient for implementability, Theorem 2 shows that 3-cycle monotonicity implies

---

\(^5\)Our results are true even if we consider intervals of the form \((0, \beta]\).

\(^6\)As defined earlier, an alternative is worthless if it can never be in the acceptable set at any dichotomous type, e.g., the alternative where a firm is not matched to any candidate in the matching model.
cycle monotonicity in rich dichotomous domains. This helps us further delineate the boundaries where weaker cycle monotonicity conditions are necessary and sufficient for implementation.

The proof of Theorem 2 relies on a particular type of payment function that we construct. For this, we define a function \( \kappa^f_i : A \rightarrow \mathbb{R}_+ \) for an allocation rule \( f \) as follows.

If \( f(s_i) \neq a \) for all \( s_i \) with \( A(s_i) = \{a\} \), then we let \( \kappa^f_i(a) = 0 \). Also, if \( a \) is a worthless alternative, then \( \kappa^f_i(a) = 0 \). Otherwise, for every other \( a \in A \), let

\[
\kappa^f_i(a) = \inf \{ v(s_i) \in V : s_i \in D_i, f(s_i) = a, A(s_i) = \{a\} \}.
\]

(2)

In words, \( \kappa^f_i(a) \) is the minimum value at which any dichotomous type containing only \( a \) in the acceptable set is satisfied. Because of our richness assumption, for all \( a \in A \), \( \kappa^f_i(a) \) is well defined. Note that \( \kappa^f_i(a) \geq 0 \) for all \( a \in A \).

Now, we define a payment function \( p^*_i \) as follows. Given an allocation rule \( f \), for every \( s_i \in D_i \), define

\[
p^*_i(s_i) = \kappa^f_i(f(s_i)) \delta(f(s_i), s_i).
\]

Note that an agent pays zero if he is not satisfied at a type.

**Proposition 2** Suppose \( f : D_i \rightarrow A \) is 2-generation monotone, where \( D_i \) is a rich dichotomous domain. Then, \( p^*_i \) implements \( f \).

**Proof:** To show that \( p^*_i \) implements \( f \), we consider two types \( t_i \) and \( s_i \) in \( D_i \). We show that

\[
v(t_i) \delta(f(t_i), t_i) - p^*_i(t_i) \geq v(t_i) \delta(f(s_i), t_i) - p^*_i(s_i)
\]

or

\[
v(t_i) - \kappa^f_i(f(t_i)) \delta(f(t_i), t_i) \geq v(t_i) \delta(f(s_i), t_i) - \kappa^f_i(f(s_i)) \delta(f(s_i), s_i).
\]

The LHS will be referred to as the payoff from truth and the RHS will be referred as the payoff from lie.

We consider various cases.

**Case 1:** Suppose \( \delta(f(t_i), t_i) = 0 \) and \( \delta(f(s_i), t_i) = 0 \). Then, the payoff from truth is zero, and the payoff from lie is non-positive. Hence, we are done.

**Case 2:** Suppose \( \delta(f(t_i), t_i) = 0 \) and \( \delta(f(s_i), t_i) = 1 \). Since \( s_i \in G^f_1(t_i) \), by GSS, \( \delta(f(s_i), s_i) = 1 \). Hence, payoff from truth is 0 and payoff from lie is \( v(t_i) - \kappa^f_i(f(s_i)) \). Assume for contradiction that \( v(t_i) > \kappa^f_i(f(s_i)) \). Consider a type \( \tilde{s}_i \) such that \( v(\tilde{s}_i) = \kappa^f_i(f(s_i)) + \epsilon < v(t_i) \), where \( \epsilon > 0 \) but arbitrarily close to zero, and \( A(\tilde{s}_i) = \{f(s_i)\} \). By definition of \( \kappa^f_i \), there is some type \( \hat{s}_i \) with \( A(\hat{s}_i) = \{f(s_i)\} \) and \( v(\hat{s}_i) \) arbitrarily close to \( \kappa^f_i(f(s_i)) \) such that \( f(\hat{s}_i) = f(s_i) \). Then, 1-generation monotonicity implies that \( f(\tilde{s}_i) = f(\hat{s}_i) = f(s_i) \). Since \( f(s_i) \in A(t_i) \), \( \tilde{s}_i \) satisfies \( t_i \). But \( \delta(f(t_i), t_i) = 0 \) implies that \( \tilde{s}_i \in G^f_1(t_i) \). By MON,
\(v(\bar{s}_i) \geq v(t_i)\). This is a contradiction. This shows that \(v(t_i) - \kappa^f_i(f(s_i)) \leq 0\), and hence, we are done.

**Case 3:** Suppose \(\delta(f(t_i), t_i) = 1\) and \(\delta(f(s_i), t_i) = 0\). In such a case, payoff from lie is non-positive. Payoff from truth is \(v(t_i) - \kappa^f_i(f(t_i))\), which we show to be non-negative. Assume for contradiction \(v(t_i) < \kappa^f_i(f(t_i))\). Consider a type \(\bar{t}_i \in \mathcal{D}_i\) such that \(v(\bar{t}_i) = v(t_i) + \epsilon\), where \(\epsilon > 0\) and arbitrarily close to zero, and \(A(\bar{t}_i) = \{f(t_i)\}\). If \(f(\bar{t}_i) \neq f(t_i)\), then \(t_i \in G_1^f(\bar{t}_i)\). But \(v(\bar{t}_i) > v(t_i)\) violates MON. Hence, \(f(\bar{t}_i) = f(t_i)\). By definition of \(\kappa^f_i\), \(v(\bar{t}_i) \geq \kappa^f_i(f(t_i))\). This is a contradiction since \(\epsilon\) is sufficiently close to zero.

**Case 4:** Suppose \(\delta(f(t_i), t_i) = 1\) and \(\delta(f(s_i), t_i) = 1\). We consider two sub-cases.

- **Case 4A:** Suppose \(\delta(f(s_i), s_i) = 0\). Then payoff from truth is \(v(t_i) - \kappa^f_i(f(t_i))\) and payoff from lie is \(v(t_i)\). We show that \(\kappa^f_i(f(t_i)) = 0\). Assume for contradiction that \(\kappa^f_i(f(t_i)) > \epsilon > 0\), where \(\epsilon\) is arbitrarily close to zero. Consider another type \(\bar{t}_i \in \mathcal{D}_i\) such that \(v(\bar{t}_i) = \kappa^f_i(f(t_i)) - \epsilon\) and \(A(\bar{t}_i) = \{f(t_i)\}\). By definition of \(\kappa^f_i\), \(f(\bar{t}_i) \neq f(t_i)\). Hence, \(t_i \in G_1^f(\bar{t}_i)\) and \(s_i \in G_2^f(\bar{t}_i)\) (since \(f(s_i) \in A(t_i)\)). By GSS, \(\delta(f(s_i), s_i) = 1\). This is a contradiction. Hence, \(\kappa^f_i(f(t_i)) = 0\), and hence, we are done.

- **Case 4B:** Suppose \(\delta(f(s_i), s_i) = 1\). Then, payoff from truth is \(v(t_i) - \kappa^f_i(f(t_i))\) and payoff from lie is \(v(t_i) - \kappa^f_i(f(s_i))\). We show that \(\kappa^f_i(f(t_i)) \leq \kappa^f_i(f(s_i))\), and we are done. If \(f(t_i) = f(s_i)\), then obviously we are done. Else, assume for contradiction \(\kappa^f_i(f(t_i)) > \kappa^f_i(f(s_i))\). Suppose \(\kappa^f_i(f(t_i)) - \kappa^f_i(f(s_i)) = \epsilon > 0\). Then, we consider two types \(\bar{t}_i\) and \(\bar{s}_i\) as follows:

\[
\begin{align*}
v(\bar{t}_i) &= \kappa^f_i(f(t_i)) - \frac{\epsilon}{3} \\
v(\bar{s}_i) &= \kappa^f_i(f(s_i)) + \frac{\epsilon}{3} \\
A(\bar{t}_i) &= \{f(t_i)\} \\
A(\bar{s}_i) &= \{f(s_i)\}.
\end{align*}
\]

By definition of \(\kappa^f_i\), \(f(\bar{t}_i) \neq f(t_i)\) and \(f(\bar{s}_i) = f(s_i)\). So, \(t_i\) satisfies \(\bar{t}_i\) and \(\bar{s}_i\) satisfies \(t_i\) (since \(f(s_i) \in A(t_i)\)). Hence, \(\bar{s}_i \in G_2^f(\bar{t}_i)\). By MON, \(v(\bar{s}_i) \geq v(\bar{t}_i)\). This is a contradiction.

\[\blacksquare\]

The proof of Theorem 2 is now immediate.
Proof of Theorem 2.

Proof: Implementability implies 3-cycle monotonicity. Proposition 1 shows that 3-cycle monotonicity implies strong 2-generation monotonicity, which implies 2-generation monotonicity. Proposition 2 shows that 2-generation monotonicity implies implementability. ■

4.1 1-Generation Monotonicity is not Sufficient

In this section, we give an example of an allocation rule in rich dichotomous domain which satisfies 1-generation monotonicity but is not implementable. Let $\mathcal{A} = \{a, b, c\}$. An allocation rule $f$ is shown in Figure 1, where all possible acceptable sets are depicted on top. The allocation rule $f$ has a cutoff for each acceptable set - for any acceptable set, a cutoff specifies a value below which the type is not satisfied and above which the type is satisfied. For example, in Figure 1, the cutoff for acceptable set $\{a\}$ is 5, that for $\{b\}$ is 2, for $\{b, c\}$ is zero, and so on. In Figure 1, these cutoffs are indicated by a dark line corresponding to each acceptable set. The outcome of the allocation rule below and above these cutoffs are shown in Figure 1. The dashed lines indicate the boundary where outcomes change (for a given acceptable set). One can verify that $f$ is 1-generation monotone.

But $f$ is not 2-generation monotone. To see this, consider a type $t_0^i$ such that $v(t_0^i) = 2 - \epsilon$, where $\epsilon > 0$ and arbitrarily close to zero, and $A(t_0^i) = \{b\}$. By definition $f(t_0^i) = c$. Now, consider a type $t_1^i$ such that $v(t_1^i) = 2 + \epsilon$ and $A(t_1^i) = \{b, c\}$. By definition $f(t_1^i) = b$. Hence, $t_1^i \in G_1^1(t_0^i)$. Finally, consider a type $t_2^i$ such that $v(t_2^i) = \epsilon$ and $A(t_2^i) = \{a, c\}$. By definition, $f(t_2^i) = c$. Hence, $t_2^i \in G_2^1(t_0^i)$. By 2-generation monotonicity, we must have $v(t_2^i) \geq v(t_0^i)$. But this is not true.

![Figure 1: A 1-generation monotone allocation rule which is not 2-generation monotone](image-url)
4.2 A Characterization Using Cutoffs

A remarkable feature of Myerson’s monotonicity characterization in the setting of single object auction is that it implies a simpler characterization using cutoffs. In particular, it says that if an allocation rule (which is deterministic) is implementable, then there must exist a cutoff value for the agent such that below this cutoff value the agent does not get the object and above this value he gets the object. The aim of this section is to give such a cutoff-based characterization in rich dichotomous domains. A cutoff-based characterization is simple to understand.

First, we define the notion of cutoffs in rich dichotomous domains. It is similar to \( \kappa_i \) that we had defined earlier.

**Definition 7** A cutoff is a mapping \( \kappa_i : \mathcal{A} \rightarrow \mathbb{R}_+ \cup \{\infty\} \) such that \( \kappa_i(a) = 0 \) for all \( a \in \mathcal{A} \) which are worthless.

Note that there may be alternatives which are not worthless and still have zero cutoff. If \( \kappa_i(a) = 0 \) then \( a \) is called a fulfilling alternative of cutoff \( \kappa_i \). A cutoff \( \kappa_i \) is a feasible cutoff if there is some alternative \( a \in \mathcal{A} \) which is fulfilling. Feasibility is trivially satisfied if there is a worthless alternative.

Given cutoffs on each alternative, we can define cutoffs on any acceptable set (i.e., any non-empty subset of alternatives). We allow for the fact that not every subset of alternatives may be an acceptable set in certain rich dichotomous domains. Indeed, our richness assumption only requires that singleton alternatives (which are not worthless) can be acceptable sets. Define the set of subsets of alternatives which can be acceptable sets as

\[
\Sigma := \{ S \subseteq \mathcal{A} : S = A(t_i) \text{ for some } t_i \in \mathcal{D}_i \}.
\]

Note that if \( S \in \Sigma \) then \( S \) does not contain any worthless alternative. By our richness assumption, if \( S \in \Sigma \), then for all possible values \( x \), \( (x, S) \in \mathcal{D}_i \). Also, if \( a \) is not a worthless alternative, then richness implies that \( \{a\} \in \Sigma \).

Now, fix a cutoff mapping \( \kappa_i \). For any acceptable set \( S \in \Sigma \), define the cutoff induced by \( \kappa_i \) on \( S \) as

\[
C^{\kappa_i}(S) = \min_{a \in S} \kappa_i(a).
\]

So, the cutoff for an acceptable set \( S \) is the minimum over cutoffs of the alternatives in \( S \). For any acceptable set \( S \in \Sigma \), let

\[
W^{\kappa_i}(S) := \{ a \in S : C^{\kappa_i}(S) = \kappa_i(a) \}.
\]

The set \( W^{\kappa_i}(S) \) contains all the alternatives in \( S \) that have the same cutoff as \( S \) itself. Note that \( W^{\kappa_i}(S) \neq \emptyset \).
Further, for every $S \in \Sigma$, let

$$ L^{\kappa_i}(S) = \{a \notin S : \kappa_i(a) = 0\}. $$

The set $L^{\kappa_i}(S)$ contains all the alternatives outside $S$ which are fulfilling. This set can be potentially empty. Note that by the definition of feasible cutoff $\kappa_i$, for any acceptable set $S \in \Sigma$, if $L^{\kappa_i}(S) = \emptyset$, then $C^{\kappa_i}(S) = 0$, and if $C^{\kappa_i}(S) > 0$, then there is some fulfilling alternative $a \notin S$ such that $\kappa_i(a) = 0$, and this implies that $L^{\kappa_i}(S) \neq \emptyset$.

Now, we are ready to formally define a cutoff-based rule, generalizing the idea of a cutoff-based rule in single object auction setting.

**Definition 8** An allocation rule $f$ is **cutoff-based** if there exists a feasible cutoff $\kappa_i$ such that at every dichotomous type $t_i \equiv (A(t_i), v(t_i))$,

1. if $v(t_i) > C^{\kappa_i}(A(t_i))$ then $f(t_i) \in A(t_i)$ and if $v(t_i) < C^{\kappa_i}(A(t_i))$ then $f(t_i) \notin A(t_i)$,

2. if $f(t_i) \in A(t_i)$ then $f(t_i) \in W^{\kappa_i}(A(t_i))$ and if $f(t_i) \notin A(t_i)$ then $f(t_i) \in L^{\kappa_i}(A(t_i))$.

In other words, a cutoff-based allocation rule specifies cutoffs for each acceptable set such that below this cutoff, types are not satisfied and above this cutoff, types are satisfied. Further, whenever a type is satisfied, the outcome must be one of the alternatives whose cutoff is equal to the cutoff of the acceptable set of this type. Whenever a type is not satisfied, the outcome must be one of the fulfilling alternatives outside the acceptable set of this type. Note how this generalizes the idea of a cutoff-based allocation rule in the single object auction model. This leads us to the main result of this section.

**Theorem 3** Suppose $D_i$ is a rich dichotomous domain. An allocation rule $f : D_i \to A$ is implementable if and only if it is cutoff-based.

The proof exploits the characterization in Theorem 2. We prove a series of claims showing the implication of 1-generation monotonicity. 1-generation monotonicity will show that for every acceptable set of alternatives, there is a cutoff value below which the type is not satisfied and above which the type is satisfied. Further, these cutoff values can be derived from the cutoffs for individual alternatives. 1-generation monotonicity also fixes the outcome at any type when it is not satisfied. Finally, we show that 2-generation monotonicity is used to fix the outcome at any type when it is satisfied. These small steps lead to the characterization of the cutoff-based rule.

**Proof:** Let $f : D_i \to A$ be an allocation rule, where $D_i$ is a rich dichotomous domain. Suppose $f$ is implementable. By Theorem 2, $f$ is 2-generation monotone. Then, we can define the cutoffs as follows. For every $S \in \Sigma$, let $C_i(S) = \infty$ if for all $t_i \in D_i$ with $A(t_i) = S$ we have $f(t_i) \notin S$. Else, define

$$ C_i(S) = \inf\{v(t_i) : t_i \in D_i, A(t_i) = S, f(t_i) \in S\}. $$

(3)
Since the domain $D_i$ is rich, for every $t_i \in D_i$ we have that $v(t_i) \in V = (0, \beta)$, and this ensures that $C_i(S) \geq 0$. Now, we make a series of claims.

**Claim 1** If $f$ is 1-generation monotone, then for every $t_i \in D_i$, $f(t_i) \in A(t_i)$ implies that $v(t_i) \geq C_i(A(t_i))$ and $f(t_i) \notin A(t_i)$ implies that $v(t_i) \leq C_i(A(t_i))$.

**Proof:** The first part follows from the definition of $C_i$. For the second part, suppose that $f(t_i) \notin A(t_i)$ and $v(t_i) > C_i(A(t_i))$. By definition of $C_i(A(t_i))$, there is some type $s_i$ such that $v(s_i)$ is arbitrarily close to $C_i(A(t_i))$ and $A(s_i) = A(t_i)$ such that $f(s_i) \in A(t_i)$. Hence, $s_i \in G_1^f(t_i)$. By 1-generation monotonicity, $v(s_i) \geq v(t_i)$, which is a contradiction since $v(s_i)$ is arbitrarily close $C_i(A(t_i))$.

**Claim 2** If $f$ is 1-generation monotone, then for every $S \in \Sigma$

$$C_i(S) = \min_{a \in S} C_i(\{a\}).$$

**Proof:** Consider any $S \in \Sigma$ and let $\min_{a \in S} C_i(\{a\}) = C_i(\{b\})$. Assume for contradiction that $C_i(S) < C_i(\{b\})$. Then, consider the type $t_i$ where $A(t_i) = S$ and $v(t_i) = C_i(S) + \epsilon < C_i(\{b\})$ (such an $\epsilon > 0$ clearly exists). By definition, $f(t_i) \in S$. Let $f(t_i) = c$. Then, $C_i(\{c\}) > v(t_i)$ implies that there is some type $s_i$ with $A(s_i) = \{c\}$ and $v(s_i) = C_i(\{c\}) - \epsilon' > v(t_i)$ such that $f(s_i) \neq c$. Hence, $t_i$ satisfies $s_i$, and $t_i \in G_1^f(s_i)$. But, 1-generation monotonicity implies that $v(t_i) \geq v(s_i)$, which is a contradiction.

Hence, $C_i(S) \geq C_i(\{b\})$. Assume for contradiction that $C_i(S) > C_i(\{b\})$. Consider two types $s_i$ and $t_i$ such that $A(s_i) = S$ and $A(t_i) = \{b\}$ but $v(s_i) = C_i(S) + \epsilon > v(t_i) = C_i(\{b\}) + \epsilon'$ (clearly, such $\epsilon, \epsilon' > 0$ exists). By definition, $f(s_i) \notin S$ and $f(t_i) = b$. This implies that $t_i \in G_1^f(s_i)$. But 1-generation monotonicity implies that $v(t_i) \geq v(s_i)$. This is a contradiction.

Using these claims, we can now define the following well-defined cutoff rule. For every $a \in A$, let

$$\kappa_i(a) = C_i(\{a\}),$$

if $a$ is not worthless, and let $\kappa_i(a) = 0$ if $a$ is worthless.

It remains to be shown that $\kappa_i$ is a feasible cutoff. For this, we use the following claim.

**Claim 3** Suppose $t_i$ is a dichotomous type such that $f(t_i) \notin A(t_i)$. If $f$ is 1-generation monotone, then $f(t_i) \in L^{\kappa_i}(A(t_i))$.

**Proof:** Suppose $t_i$ is a dichotomous type such that $f(t_i) = a \notin A(t_i)$. Assume for contradiction that $a \notin L^{\kappa_i}(A(t_i))$. This means $\kappa_i(a) > 0$, and hence, $a$ is not a worthless alternative. Consider a dichotomous type $\bar{t}_i$ such that $A(\bar{t}_i) = \{a\}$ and $v(\bar{t}_i) < \kappa_i(a)$. By definition,
\( f(\tilde{t}_i) \neq a \). Hence, \( t_i \in G_1^i(\tilde{t}_i) \). By 1-generation monotonicity (GSS), \( t_i \) must satisfy itself. This is a contradiction.  

Now, to see that \( \kappa_i \) is a feasible cutoff, assume for contradiction that it is not. Then, for every alternative \( a \in A, \kappa_i(a) > 0 \). Pick any \( a \in A \). Since \( \kappa_i(a) > 0 \), for any dichotomous type \( t_i \) such that \( v(t_i) < \kappa_i(a) \) and \( A(t_i) = \{a\} \), \( f(t_i) \neq a \) (by Claim 1). By Claim 3, \( f(t_i) \in L^{\kappa_i}(\{a\}) \). But, by our assumption \( L^{\kappa_i}(\{a\}) = \emptyset \). This is a contradiction.

We now prove another claim.

**Claim 4** Suppose \( t_i \) is a dichotomous type such that \( f(t_i) \in A(t_i) \). If \( f \) is 2-generation monotone, then \( \kappa_i(f(t_i)) \leq \kappa_i(a) \) for all \( a \in A(t_i) \).

**Proof:** Let \( t_i \) be a dichotomous type such that \( A(t_i) = S \) and \( f(t_i) = b \in S \). Choose \( a \in S \setminus \{b\} \). Assume for contradiction that \( \kappa_i(b) - \kappa_i(a) > \epsilon > 0 \) for some \( \epsilon \). Consider two dichotomous types \( \tilde{t}_i \) and \( \hat{t}_i \) such that

\[
\begin{align*}
v(\tilde{t}_i) &= \kappa_i(b) - \frac{\epsilon}{2}, A(\tilde{t}_i) = \{b\} \\
v(\hat{t}_i) &= \kappa_i(a) + \frac{\epsilon}{2}, A(\hat{t}_i) = \{a\}.
\end{align*}
\]

By definition, \( f(\tilde{t}_i) \neq b \) and \( f(\hat{t}_i) = a \). Hence, \( t_i \in G_1^i(\tilde{t}_i) \) and \( \hat{t}_i \in G_2^i(\hat{t}_i) \). By 2-generation monotonicity, \( \kappa_i(a) + \frac{\epsilon}{2} \geq \kappa_i(b) - \frac{\epsilon}{2} \). Hence, \( \kappa_i(b) - \kappa_i(a) \leq \epsilon \), which is a contradiction.

Claim 4 establishes that if for any dichotomous type \( t_i \) we have \( f(t_i) \in A(t_i) \), then \( \kappa_i(f(t_i)) = \min_{a \in A(t_i)} \kappa_i(a) \). Hence, \( f(t_i) \in W^{\kappa_i}(A(t_i)) \). This establishes that if \( f \) is implementable then it is cutoff-based.

We now show that if \( f \) is cutoff-based then it is implementable. Let the feasible cutoff corresponding to \( f \) be \( \kappa_i \). We show that \( f \) is 2-generation monotone. Consider \( t_i \) such that \( f(t_i) \notin A(t_i) \) and let \( s_i \in G_1^i(t_i) \). Assume for contradiction that \( f(s_i) \notin A(s_i) \). By the definition of cutoff-based rule, \( f(s_i) \in L^{\kappa_i}(A(s_i)) \). This implies that \( \kappa_i(f(s_i)) = 0 \). But \( f(s_i) \in A(t_i) \) implies that \( \min_{a \in A(t_i)} \kappa_i(a) = C^{\kappa_i}(A(t_i)) = 0 \). Since, \( f \) is cutoff-based, this means \( f(t_i) \in A(t_i) \). This is a contradiction. So, \( f(s_i) \in A(s_i) \). Now, using the definition of cutoff-based rule and the definition of \( C^{\kappa_i}(\cdot) \),

\[
v(s_i) \geq C^{\kappa_i}(A(s_i)) = \kappa_i(f(s_i)) \geq C^{\kappa_i}(A(t_i)) \geq v(t_i).
\]

This shows that \( f \) is 1-generation monotone.

Now, consider \( s_i \) such that \( s_i \in G_2^i(t_i) \). Assume for contradiction that \( f(s_i) \notin A(s_i) \). In that case, \( \kappa_i(f(s_i)) = 0 \). But \( f(s_i) \in A(s_i) \) implies that \( C^{\kappa_i}(A(s_i)) = 0 \). But we know that \( s_i \) satisfies itself, and hence, \( \kappa_i(f(s_i)) = C^{\kappa_i}(A(s_i)) = 0 \) (by the definition of cut-off based rule). Then, consider any type \( \tilde{t}_i \) with \( A(\tilde{t}_i) = \{f(s_i)\} \) and \( 0 < v(\tilde{t}_i) < v(t_i) \). By definition, \( f(\tilde{t}_i) = f(s_i) \in A(t_i) \). Hence, \( \tilde{t}_i \in G_1^i(t_i) \). By 1-generation monotonicity, \( v(\tilde{t}_i) \geq v(t_i) \).
This is a contradiction. Hence, \( f(\bar{s}_i) \in A(\bar{s}_i) \). By the definition of cutoff-based rule and the definition of \( C^\kappa_i(\cdot) \),

\[
v(\bar{s}_i) \geq \kappa_i(f(\bar{s}_i)) \geq C^\kappa_i(A(s_i)) = \kappa_i(f(s_i)) \geq C^\kappa_i(A(t_i)) \geq v(t_i).
\]

This shows that \( f \) is 2-generation monotone.

**Remark.** The proof shows what 1-generation monotonicity alone gives us, and the additional implication of 2-generation monotonicity. It is clear that 2-generation monotonicity is only used to fix the outcome when a dichotomous type is satisfied. When a dichotomous type is satisfied, it must be satisfied only by an alternative in the acceptable set whose cutoff value is the same as the cutoff value of the acceptable set.

Using Theorem 3, we can now fix the allocation rule in Figure 1. Since this allocation rule already satisfies 1-generation monotonicity, the only modification we need to do is to assign the correct outcome using Theorem 3 when a dichotomous type is satisfied. This is shown in Figure 2.

Using Theorem 3, we can now fix the allocation rule in Figure 1. Since this allocation rule already satisfies 1-generation monotonicity, the only modification we need to do is to assign the correct outcome using Theorem 3 when a dichotomous type is satisfied. This is shown in Figure 2.

**4.3 Revenue Equivalence**

In this section, we establish that revenue equivalence holds in rich dichotomous domains. The seminal revenue equivalence result of Myerson (1981) has been extended to the multidimensional set up by many authors - see for example, Milgrom and Segal (2002), Krishna and Maenner (2001), Chung and Olszewski (2007), and Heydenreich et al. (2009). These papers establish that every implementable allocation rule satisfies revenue equivalence if the domain satisfies certain assumptions. The assumptions in these papers require that the domain be connected.

However, our domain is not connected. To see this, consider an example with three alternatives: \( \mathcal{A} = \{a, b, c\} \). Suppose all possible acceptable sets are permissible, i.e. \( \Sigma = \)
\{S : S \subseteq \mathcal{A}, S \neq \emptyset\}$. Suppose the value at any dichotomous type lies in $(0, \infty)$. Then, the type space in $\mathbb{R}^3$ is shown in Figure 3. It consists of seven open rays originating from the origin (but not including the origin). The positive parts of the three axes constitute three rays, and they refer to those dichotomous types where there is a single acceptable alternative. The positive parts of the 45-degree rays in $xy, yz, zx$ planes are three more rays, and they refer to those dichotomous types where the acceptable set consists of any two alternatives. Finally, the positive part of the ray from the origin and passing through $(1, 1, 1)$ consists of all dichotomous types where the acceptable set is $\{a, b, c\}$. Note that this type space is not connected since the origin is not part of it.

![Figure 3: A rich dichotomous domain with three alternatives](image)

Heydenreich et al. (2009) give a condition for the allocation rule (instead of domain) such that it satisfies revenue equivalence. We use this result in Heydenreich et al. (2009) to prove revenue equivalence in rich dichotomous domains.

**Theorem 4** If $f : \mathcal{D}_i \rightarrow \mathcal{A}$ is an implementable allocation rule, where $\mathcal{D}_i$ is a rich dichotomous domain, and $p_i$ implements $f$ then

$$p_i(t_i) = \kappa_i^f(f(t_i))\delta(f(t_i), t_i) + c_i \quad \forall \ t_i \in \mathcal{D}_i,$$

where $c_i$ is a constant and $\kappa_i^f$ is as defined in Equation 2.

The proof of Theorem 4 is given in the Appendix. We use this result in Section 6 to determine a revenue maximizing mechanism in a one-sided matching model with agents having dichotomous types.
5 Extension to $n$ Agents

In this section, we show how our results can be extended to a setting with more than one agent. Suppose $N = \{1, \ldots, n\}$ be the set of $n$ agents. An allocation rule $f$ in the dichotomous domain will now be a mapping $f : \mathcal{D} \rightarrow \mathcal{A}^n$, where $\mathcal{D} = \mathcal{D}_1 \times \mathcal{D}_2 \times \ldots \times \mathcal{D}_n$ denotes the set of all dichotomous type profiles. Note that the outcome of an allocation rule is in $\mathcal{A}^n$. So, an allocation rule specifies an alternative for each agent at every type profile. We denote the allocation of agent $i$ at type profile $t$ as $f_i(t) \in \mathcal{A}$. We assume absence of allocative externality. So, the value of an agent is completely determined by his own allocation.

There may be feasibility constraints linking the allocations of different agents at each type profile. For instance, in the collective choice problems, such as the problems of hiring a staff jointly by departments and choosing a network to build, all agents must get the same alternative as allocation, i.e., for every type profile $t$, we must have $f_i(t) = f_j(t)$ for all $i, j \in N$. The richness restriction (b) in Section 4 applies to the set of alternatives $\mathcal{A}$.

On the other hand, in private good problems, like single-minded combinatorial auction or matching with transfers, each agent $i$ is faced with a set of alternatives $\mathcal{A}$. In the case of single-minded combinatorial auction, $\mathcal{A}$ is the set of all subsets of objects. In the case of matching with transfers in job market, the set of alternatives for a firm is the set of all job candidates. An allocation rule chooses an alternative in $\mathcal{A}$ for every agent such that it constitutes a feasible outcome, e.g., in case of matching it is a feasible matching (no candidate is assigned more than one job). The richness restriction (b) in Definition 6 applies to the set of alternatives $\mathcal{A}$. With this interpretation, all our definitions and results extend easily.

An allocation rule $f$ is implementable if there exists payment functions $p_1, \ldots, p_n$, where $p_i : \mathcal{D} \rightarrow \mathbb{R}$ for all $i \in N$, such that for every $i \in N$ and every $t_{-i}$, we have

$$v_i(t_i)\delta(f_i(t_i, t_{-i}), t_i) - p_i(t_i, t_{-i}) \geq v_i(t_i)\delta(f_i(s_i, t_{-i}), t_i) - p_i(s_i, t_{-i}) \quad \forall s_i, t_i \in \mathcal{D}_i.$$

An allocation rule $f$ is $K$-cycle monotone, where $K$ is a positive integer not less than two, if for every agent $i \in N$, every $t_{-i}$, and for every sequence of types $(t_i^1, t_i^2, \ldots, t_i^k)$ with $k \leq K$, we have

$$\ell_{t_i}^f(t_i^1, t_i^2) + \ldots + \ell_{t_i}^f(t_i^{k-1}, t_i^k) + \ell_{t_i}^f(t_i^k, t_i^1) \geq 0.$$

An allocation rule $f$ is cyclically monotone if it is $K$-cycle monotone for all positive integers $K \geq 2$. 

22
We can also extend the notion of generations with many agents. Given an allocation rule $f$, a type $t_i$ is **satisfied** by $s_i$ at $t_{-i}$ if $\delta(f_i(s_i, t_{-i}), t_i) = 1$. If $\delta(f_i(t_i, t_{-i}), t_i) = 1$, we say that $t_i$ is satisfied (by itself) at $t_{-i}$. If $t_i$ is not satisfied at $t_{-i}$, then we say it is unsatisfied at $t_{-i}$.

Define the first generation types of an unsatisfied type $t_i \in \mathcal{D}_i$ at $t_{-i}$ in $f$ as

$$G^{{f,t_{-i}}}_1(t_i) = \{ s_i \in \mathcal{D}_i : \delta(f_i(s_i, t_{-i}), t_i) = 1 \}.$$ 

Having defined the $k$-th generation types of the unsatisfied type $t_i$ at $t_{-i}$, we define the $(k + 1)$-st generation types of $t_i$ at $t_{-i}$ as follows

$$G^{{f,t_{-i}}}_{k+1}(t_i) = \{ s_i \in \mathcal{D}_i \setminus \bigcup_{j=1}^k G^{{f,t_{-i}}}_j(t_i) : \delta(f_i(s_i, t_{-i}), t_i) = 1 \text{ for some } \bar{t}_i \in G^{{f,t_{-i}}}_k(t_i) \}.$$ 

For every $t_{-i}$, it is possible that for some $t_i \in \mathcal{D}_i$ and some positive integer $k$, $G^{{f,t_{-i}}}_k(t_i) = \emptyset$. The notion of generation number can also be extended analogously. Generation number $\gamma^{{f,t_{-i}}}(t_i)$ of an unsatisfied type $t_i$ at $t_{-i}$ is the largest positive integer $k$ such that $G^{{f,t_{-i}}}_k(t_i) \neq \emptyset$. Generation number $\gamma^f$ is defined as

$$\gamma^f := \max_{i \in \mathcal{N}} \max_{(t_i, t_{-i}) \in \mathcal{D}_i, f_i(t_i, t_{-i}) \notin A(t_i)} \gamma^{{f,t_{-i}}}(t_i).$$

The definition of generation monotonicity can then be extended straightforwardly.

**Definition 9** An allocation rule $f$ is **$K$-generation monotone**, where $K$ is a positive integer, if for every agent $i \in \mathcal{N}$, every $t_{-i}$, and for every unsatisfied type $t_i \in \mathcal{D}_i$ at $t_{-i}$ and every positive integer $k \leq K$, the following holds for all $s_i \in G^{{f,t_{-i}}}_k(t_i)$

1. **Generation Self Satisfaction (GSS)**. $s_i$ is satisfied at $t_{-i}$,

2. **Monotonicity (MON)**. $v(s_i) \geq v(t_i),$

An allocation rule $f$ is **generation monotone** if it is $K$-generation monotone for all positive integers $K$.

An allocation rule $f$ is **strong $K$-generation monotone**, where $K$ is a positive integer, if it is $K$-generation monotone and for every agent $i \in \mathcal{N}$, every $t_{-i}$, and for every unsatisfied type $t_i \in \mathcal{D}_i$ at $t_{-i}$ and every positive integer $k \leq K$, the following holds for all $s_i \in G^{{f,t_{-i}}}_k(t_i),$

1. **No Rebirth (NR)**. $t_i$ does not satisfy $s_i$ at $t_{-i}$.

An allocation rule $f$ is **strong generation monotone** if it is strong $K$-generation monotone for all positive integers $K$.

With these changes in definitions, all our results can be straightforwardly extended to the $n$-agents case.

We highlight two important modifications that need to be made. First, in the $n$-agent model, cutoffs are always defined on $\mathcal{A}$. These cutoffs are also specific to every agent $i$ and
every type profile \( t_{-i} \) of other agents. So, \( \kappa_{i,t_{-i}} : \mathcal{A} \to \mathbb{R}_+ \cup \{\infty\} \) defines a cutoff mapping, and Theorem 3 can now be modified keeping this in mind.

Second, the revenue equivalence result in Theorem 4 can be extended when there are \( n \) agents. The only difference in Theorem 4 will be that instead of arbitrary constants \( c_i \) for every agent \( i \in N \), we will now have a function \( c_i : \mathcal{D}_{-i} \to \mathbb{R} \), where \( \mathcal{D}_{-i} \) is the set of dichotomous type profiles of agents other than agent \( i \).

6 Application: Revenue Maximizing Matching with Dichotomous Preferences

In this section, we apply our results on characterizing implementable allocation rules in rich dichotomous domains. We derive an optimal mechanism in a one-sided matching problem where agents have dichotomous types. We will assume that the set of alternatives is \( \mathcal{A} \), and this includes a worthless alternative \( a_0 \). We will denote the set of alternatives without \( a_0 \) as \( \mathcal{A}_0 \equiv \mathcal{A} \setminus \{a_0\} \). The interpretation of \( \mathcal{A}_0 \) can be a set of objects (time periods where an airline ticket is available or schools to which a student can be assigned etc). The worthless alternative \( a_0 \) can be interpreted as the alternative where an agent is not assigned any object. Let \( N = \{1, \ldots, n\} \) be the set of \( n \) agents. The acceptable set of each agent \( i \in N \) is a subset of \( \mathcal{A}_0 \). Using our earlier notation, we let \( \Sigma := \{A \subseteq \mathcal{A}_0 : A \neq \emptyset\} \). We assume that at any dichotomous type, the value of any agent \( i \in N \) lies in the interval \( V_i = (0, \beta_i) \), where \( \beta_i \in \mathbb{R}_+ \cup \{\infty\} \). This ensures that the type space of every agent is a rich dichotomous domain. We refer to this problem as the one-sided matching with dichotomous preferences.

An allocation rule \( f \) is a mapping \( f : \mathcal{D} \to \mathcal{A}^n \). So, \( f \) assigns each agent an alternative in \( \mathcal{A} \) - this is a private good allocation problem. There may be feasibility constraints. For instance, there may be a finite number of units of every object. In the example of students matching to schools, a school may have a capacity constraint on the number of students they can take. In the example of agents assigned to different time periods of an airline, the number of tickets available in a time period may be finite. We denote such constraints on the outcome of \( f \) as \( \mathcal{F} \), and assume that there is no restriction on number of agents who can be assigned the alternative \( a_0 \). An outcome of an allocation rule is an element of \( \mathcal{A}^n \) satisfying feasibility constraints of \( \mathcal{F} \), and will be called an assignment.

We assume that the type of each agent’s type is drawn independently as follows. The probability that \( A \subseteq \mathcal{A}_0 \) is the acceptable set of agent \( i \) is given by \( h_i(A) \). The value of agent \( i \) is drawn using a distribution \( g_i \) with cdf \( G_i \). Note that we assume that the value of agent \( i \) is independent of his acceptable set. We assume that the hazard rate \( \frac{g_i(v_i)}{1-G_i(v_i)} \) is non-decreasing in \( v_i \). Let \( w_i : V_i \to \mathbb{R} \) be the virtual valuation function of agent \( i \), defined as

\[
w_i(v_i) = v_i - \frac{1 - G_i(v_i)}{g_i(v_i)} \quad \forall \ v_i \in V_i.
\]
Since the hazard rate is non-decreasing, the virtual valuation function is increasing.

Now, fix an allocation rule $f$. We denote the alternative assigned to agent $i$ at any type profile $t$ as $f_i(t)$. Suppose $f$ is implementable and $p \equiv (p_1, \ldots, p_n)$ implements $f$. In such a case, we will say that the mechanism $(f, p)$ is dominant strategy incentive compatible (DSIC). Then, the expected revenue in mechanism $(f, p)$ is given by

$$
\Pi(f, p) = \sum_{i \in N} E_i[p_i(t)],
$$

where $E_i[\cdot]$ denotes the expectation over all the type profiles. A mechanism $(f, p)$ is individually rational if at every type profile $t \in D$, we have $v(t_i)\delta(f_i(t), t_i) - p_i(t) \geq 0$ for all $i \in N$.

**Definition 10** A mechanism $(f, p)$ is an optimal mechanism if it is DSIC, individually rational, and there does not exist another mechanism $(f', p')$ such that $(f', p')$ is DSIC, individually rational, and $\Pi(f', p') > \Pi(f, p)$.

Consider a DSIC mechanism $(f, p)$ and a rich dichotomous type profile $t \equiv (t_1, \ldots, t_n)$. By Theorem 4, the payment of agent $i \in N$ at type profile $t$ is given by

$$
p_i(t) = c_i(t_{-i}) + \kappa_{i,t_{-i}}^f(f_i(t))\delta(f_i(t), t_i),
$$

(4)

where $\kappa_{i,t_{-i}}^f$ is the cutoff of agent $i$ corresponding to the allocation rule $f$ (as defined in Equation 2) and $c_i : D_{-i} \to \mathbb{R}$ is an arbitrary function. Using the definition of cutoff $\kappa_{i,t_{-i}}^f(f_i(t))$ and our characterization result of Theorem 3, we know that for any dichotomous type with $A(t_i)$ as acceptable set, agent $i$ is satisfied at all values above $\kappa_{i,t_{-i}}^f(f_i(t))$ and is not satisfied at all values below $\kappa_{i,t_{-i}}^f(f_i(t))$. Hence, we can write the payment of agent $i$ at type profile $t$ as

$$
p_i(t) = c_i(t_{-i}) + v(t_i)\delta(f_i(t), t_i) - \int_0^{v(t_i)} \delta(f_i((x_i, A(t_i)), t_{-i}), (x_i, A(t_i)))dx_i,
$$

(5)

where we write $(x_i, A(t_i))$ to denote a dichotomous type with value $x_i$ and acceptable set $A(t_i)$. To see how Equations 4 and 5 are equivalent, note that by our characterization of implementable rule using cutoffs in Theorem 3, we can conclude that the value of the integral in Equation 5 is 0 if $\delta(f_i(t), t_i) = 0$ and $[v(t_i) - \kappa_{i,t_{-i}}^f(f_i(t))]$ if $\delta(f_i(t), t_i) = 1$.

Once we have the expression for the payment in this form, we employ the methodology of Myerson (1981) to express the expected revenue in terms of virtual valuations. The expected
payment of agent $i$ in the DSIC mechanism $(f, p)$ is given by

$$
\pi_i(f, p) = E_{t-i} \left[ c_i(t_{-i}) + \sum_{A \in A_0} \left[ \int_0^{\beta_i} z_i \delta(f_i((z_i, A), t_{-i}),(z_i, A)) g_i(z_i) dz_i - \int_0^{\beta_i} \left( \int_0^{z_i} \delta(f_i((x_i, A), t_{-i}),(x_i, A)) dx_i \right) g_i(z_i) dz_i \right] h_i(A) \right]
$$

$$
= E_{t-i} \left[ c_i(t_{-i}) + \sum_{A \in A_0} \left[ \int_0^{\beta_i} z_i \delta(f_i((z_i, A), t_{-i}),(z_i, A)) g_i(z_i) dz_i - \int_0^{z_i} (1 - G_i(z_i)) \delta(f_i((z_i, A), t_{-i}),(z_i, A)) dz_i \right] h_i(A) \right]
$$

$$
= E_{t-i} \left[ c_i(t_{-i}) + \sum_{A \in A_0} \left[ \int_0^{\beta_i} \left( z_i - \frac{1 - G_i(z_i)}{g_i(z_i)} \right) \delta(f_i((z_i, A), t_{-i}),(z_i, A)) g_i(z_i) dz_i \right] h_i(A) \right].
$$

Hence, the expected revenue in the DSIC mechanism $(f, p)$ is given by

$$
\Pi(f, p) = \sum_{i \in N} E_{t-i} \left[ c_i(t_{-i}) + \sum_{A \in A_0} \left[ \int_0^{\beta_i} w_i(z_i) \delta(f_i((z_i, A), t_{-i}),(z_i, A)) g_i(z_i) dz_i \right] h_i(A) \right].
$$

Note that if $(f, p)$ is individually rational, then for every $i \in N$ and every $t_{-i}$, we have $c_i(t_{-i}) \leq 0$. If $(f, p)$ is individually rational and we want to maximize the expected revenue, then we must have $c_i(t_{-i}) = 0$ for all $i \in N$ and for all $t_{-i}$. Using this, the expression of the expected revenue in the DISC mechanism $(f, p)$ is reduced to

$$
\Pi(f, p) = \sum_{i \in N} E_{t-i} \left[ \sum_{A \in A_0} \left[ \int_0^{\beta_i} w_i(z_i) \delta(f_i((z_i, A), t_{-i}),(z_i, A)) g_i(z_i) dz_i \right] h_i(A) \right]
$$

$$
= E_t \left[ \sum_{i \in N} w_i(v(t_i)) \delta(f_i(t), t_i) \right]
$$

If we sidestep the fact that $f$ needs to be 2-generation monotone (for it to be implementable), the above expression can be maximized by doing point-wise maximization. So, at every type profile, we look at those agents whose virtual values are non-negative. For any agent whose virtual valuation is not positive, he is assigned the alternative $a_0$. Else, an alternative $a^i \in A$ is assigned to agent $i$ such that $(a^1, \ldots, a^n) \in c$ (i.e., a feasible allocation), and the sum of virtual values of all the agents who have positive virtual values is maximized from this allocation. Formally, at every type profile $t \in D$, let $W(t) := \{i \in N : w_i(v(t_i)) > 0\}$. The optimal allocation rule $f^*$ is defined as follows. For every type profile $t$, denote by $A^n(t) \subseteq A^n$ be the set of feasible assignments where each agent $i \notin W(t)$ is assigned the worthless alternative $a_0$. In other words, at every type profile $t$, if we take any $a \in A^n(t)$, then for every $i \notin W(t)$, we have $a^i = a_0$, where $a^i$ is the alternative assigned to agent $i$ in assignment $a$. Then, $f^*$ is defined as,
\[f^*(t) = \arg \max_{(a^1, \ldots, a^s) \in \mathcal{A}^s(t)} \left[ \sum_{i \in \mathcal{W}(t)} w_i(v(t_i))\delta(a^i, A(t_i)) \right], \tag{6}\]

where we assume \(f^*_i(t) = a_0\) if \(\delta(f^*_i(t), t_i) = 0\), i.e., if an agent is unsatisfied then he is assigned \(a_0\) (note that this does not influence the outcome of the maximization). We show that \(f^*\) is implementable.

**Proposition 3** The allocation rule \(f^*\) is implementable.

**Proof:** Using Theorem 2, we only need to show that \(f^*\) satisfies 2-generation monotonicity. Fix an agent \(i\) and type profile \(t_{-i}\) of other agents. Let \(t_i\) be a type of agent \(i\) such that \(f^*_i(t_i, t_{-i}) = a_0\). Suppose \(s_i\) is a 1st generation type of \(t_i\) at \(t_{-i}\). Then \(f^*_i(s_i, t_{-i}) \in \mathcal{A}(t_i)\). This implies that \(f^*_i(s_i, t_{-i}) \neq a_0\) and \(f^*_i(s_i, t_{-i}) \notin \mathcal{A}(s_i)\) (since the virtual valuation function is increasing). This establishes \(\text{GSS}\).

Now, for 2-generation monotonicity consider \(s_i'\) which is a 2nd generation type of \(t_i\) at \(t_{-i}\). Suppose \(s_i'\) satisfies \(s_i\), where \(s_i\) is a 1st generation type of \(t_i\). Note that since \(f^*_i(s_i', t_{-i}) \in \mathcal{A}(s_i)\), \(f^*_i(s_i', t_{-i}) \neq a_0\), and by the definition of \(f^*\), we have \(f^*_i(s_i', t_{-i}) \in \mathcal{A}(s_i')\). This establishes \(\text{GSS}\).

Since \(f^*_i(s_i', t_{-i}) \in \mathcal{A}(s_i')\), this means \(w_i(v(s_i')) > 0\). If \(w_i(v(t_i)) \leq 0\), then \(v(s_i') > v(t_i)\) (since the virtual valuation function is increasing). Consider the case where \(w_i(v(t_i)) > 0\). Suppose the allocation of any agent \(j \in N\) in type profile \((t_i, t_{-i})\) is \(T_j\), in type profile

\[w_i(v(t_i))\delta(T_i, t_i) + \sum_{j \in \mathcal{W}(t_{-i})} w_j(v(t_j))\delta(T_j, t_j) \geq w_i(v(t_i))\delta(S_i, t_i) + \sum_{j \in \mathcal{W}(t_{-i})} w_j(v(t_j))\delta(S_j, t_j)\]

\[w_i(v(s_i))\delta(S_i, s_i) + \sum_{j \in \mathcal{W}(t_{-i})} w_j(v(t_j))\delta(S_j, t_j) \geq w_i(v(s_i))\delta(T_i, s_i) + \sum_{j \in \mathcal{W}(t_{-i})} w_j(v(t_j))\delta(T_j, t_j).\]

Adding these two inequalities, and using the fact that \(\delta(T_i, t_i) = 0\), \(\delta(S_i, t_i) = 1\), and \(\delta(S_i, s_i) = 1\) we get

\[w_i(v(s_i)) - w_i(v(s_i))\delta(T_i, s_i) \geq w_i(v(t_i)).\]

Since \(w_i(v(t_i)) > 0\), the above inequality is feasible only if \(\delta(T_i, s_i) = 0\) and \(v(s_i) \geq v(t_i)\). This establishes MON. Hence, \(f^*\) is 1-generation monotone.

Now, for 2-generation monotonicity consider \(s_i'\) which is a 2nd generation type of \(t_i\) at \(t_{-i}\). Suppose \(s_i'\) satisfies \(s_i\), where \(s_i\) is a 1st generation type of \(t_i\). Note that since \(f^*_i(s_i', t_{-i}) \in \mathcal{A}(s_i)\), \(f^*_i(s_i', t_{-i}) \neq a_0\), and by the definition of \(f^*\), we have \(f^*_i(s_i', t_{-i}) \in \mathcal{A}(s_i')\). This establishes \(\text{GSS}\).

Since \(f^*_i(s_i', t_{-i}) \in \mathcal{A}(s_i')\), this means \(w_i(v(s_i')) > 0\). If \(w_i(v(t_i)) \leq 0\), then \(v(s_i') > v(t_i)\) (since the virtual valuation function is increasing). Consider the case where \(w_i(v(t_i)) > 0\). Suppose the allocation of any agent \(j \in N\) in type profile \((t_i, t_{-i})\) is \(T_j\), in type profile

27
\((s_i, t_{-i})\) is \(S_j\), and in type profile \((s'_i, t_{-i})\) is \(S'_j\). Using the definition of \(f^*\), we get the following inequalities.

\[
 w_i(v(t_i))\delta(T_i, t_i) + \sum_{j \in W(t_{-i})} w_j(v(t_j))\delta(T_j, t_j) \geq w_i(v(t_i))\delta(S_i, t_i) + \sum_{j \in W(t_{-i})} w_j(v(t_j))\delta(S_j, t_j)
\]

\[
 w_i(v(s_i))\delta(S_i, s_i) + \sum_{j \in W(t_{-i})} w_j(v(t_j))\delta(S_j, t_j) \geq w_i(v(s_i))\delta(S'_i, s_i) + \sum_{j \in W(t_{-i})} w_j(v(t_j))\delta(S'_j, t_j)
\]

\[
 w_i(v(s'_i))\delta(S'_i, s'_i) + \sum_{j \in W(t_{-i})} w_j(v(t_j))\delta(S'_j, t_j) \geq w_i(v(s'_i))\delta(T_i, s'_i) + \sum_{j \in W(t_{-i})} w_j(v(t_j))\delta(T_j, t_j).
\]

Using the facts that \(\delta(S_i, s_i) = \delta(S'_i, s_i) = \delta(S'_i, s'_i) = 1\) and \(\delta(T_i, t_i) = 0\), and adding the above inequalities we get that

\[
 w_i(v(s'_i)) - w_i(v(s'_i))\delta(T_i, s'_i) \geq w_i(v(t_i)).
\]

Since \(w_i(v(t_i)) > 0\), the above inequality is feasible only if \(\delta(T_i, s'_i) = 0\) and \(v(s'_i) \geq v(t_i)\). This establishes MON. Hence, \(f^*\) is 2-generation monotone.

This shows that \(f^*\) along with the cutoff payment defined in Proposition 2 is the optimal mechanism. This is summarized in the following theorem.

**Theorem 5.** *In the one-sided matching problem with dichotomous preferences, the optimal mechanism is given by \((f^*, p^*)\), where \(f^*\) is defined as in Equation 6, and for every \(t \in \mathcal{D}\) and every \(i \in \mathcal{N}\), \(p^*_i(t) = \kappa_t^{f^*}(f^*_i(t), t_i)\), where \(\kappa_t^{f^*}\) is defined as in Equation 2.*

**Remark.** One notices that the optimal mechanism is independent of the probability distribution of acceptable sets. Intuitively, the payments are determined by cutoffs of values. Revenue maximization is therefore related to how values are distributed. Since we assumed the value distribution is independent of the distribution of acceptable sets, the optimal mechanism is only dependent on the distribution of values.

**Remark.** A special case of the optimal mechanism occurs when there is just one agent. This problem is referred to as the revenue maximization of a multiple good monopolist seller, and is recognized as a hard problem if the type of the buyer is multidimensional (Manelli and Vincent, 2007). Theorem 5 says that if there is one agent \(i\), then the optimal mechanism is to set a reserve price equal to \(r^*\) which solves \(r^* = 1 - \frac{G_i(r^*)}{y_i(r^*)}\) - there is a unique solution to this if the hazard rate is non-decreasing. Agent \(i\) is satisfied by allocating any alternative in his acceptable set if his value is above \(r^*\), and not satisfied by allocating \(a_0\) if his value is less than or equal to \(r^*\).

**Remark.** Unlike Myerson (1981), who searched for optimal mechanism in the single object auction case over all Bayesian incentive compatible and randomized mechanisms, we are
searching over all DSIC and deterministic mechanisms. Most of the literature on optimal mechanism design in multidimensional type spaces also consider Bayes-Nash randomized implementation (for example, Iyengar and Kumar (2008) and Pai and Vohra (2008)). For single object auctions, this restriction is without loss of generality since the optimal mechanism is a DSIC and deterministic mechanism - see a more general result for the single object auction case in Manelli and Vincent (2010). However, we do not know if we enlarge our search to include Bayesian incentive compatible and randomized mechanisms, we will improve expected revenues in this setting.

7 Conclusion

The seminal paper of Myerson (Myerson, 1981) contained three important results in mechanism design in quasi-linear environments for the single object auction case: (1) a characterization of implementable allocation rules; (2) illustration of revenue equivalence; (3) derivation of optimal mechanism. Each of these results have been generalized to various multidimensional settings. We contribute to this literature by extending these results to specific dichotomous domains.

Our general methodology in the paper is to derive a simplification of cycle monotonicity in the specific multidimensional dichotomous domains. Whether we can derive similar simplifications in other interesting non-convex domains, and then use it to derive an easy characterization of implementability remains an open question. It will also be interesting to extend our results with randomization and/or considering relaxed form of implementability like Bayes-Nash implementability.

APPENDIX 1: OMITTED PROOFS

Proof of Lemma 1

Proof: Let $K = |A|$, and let $f$ be a $K$-cycle monotone allocation rule. Consider any cycle $C \equiv (t^1_i, \ldots, t^k_i, t^1_i)$ in the type graph. We do the proof by induction on $k$. If $k \leq K$, then by definition this cycle has non-negative length. Suppose $k > K$, and assume that all cycles with less than $k$ nodes have non-negative length. Since $k > K$, there are two types $t^h_i$ and $t^j_i$ in the cycle $C$ such that $f(t^h_i) = f(t^j_i)$. Note that the length of the edges $(t^h_i, t^{j+1}_i)$ and $(t^{j}_i, t^h_i)$ are both zero. Assume without loss of generality $h < j$. We consider two cases.

Case 1: If $h = j - 1$, then note that the length of the edge $(t^h_i, t^{j+1}_i)$ is the same as the length of the edge $(t^j_i, t^{j+1}_i)$. Hence, the length of the cycle $C' \equiv (t^1_i, \ldots, t^h_i, t^{j+1}_i, \ldots, t^k_i, t^1_i)$ is the same as the length of the cycle $C$. But $C'$ has one less node than $C$. By our induction hypothesis, the length of cycle $C'$ is non-negative. So, the length of cycle $C$ is non-negative.
Case 2: If $h = 1$ and $j = k$, then we repeat Case 1, but this time we consider the cycle $C' \equiv (t_i^2, \ldots, t_i^k, t_i)$.

Case 3: In this case, there is at least one node between $t_i^h$ and $t_i^k$, and at least one node between $t_i^k$ and $t_i^h$ in cycle $C$. We can now break the cycle $C$ into two parts $C^1 \equiv (t_i^1, \ldots, t_i^h, t_i^h+1, \ldots, t_i^k, t_i)$ and $C^2 \equiv (t_i^h, t_i^{h+1}, \ldots, t_i^k, t_i^k)$. Since $f(t_i^h) = f(t_i^k)$, the edges $(t_i^h, t_i^h)$ and $(t_i^k, t_i^k)$ have zero length. Hence, the total length of both the cycles $C^1$ and $C^2$ combined is equal to the length of the cycle $C$. Further, $C^1$ and $C^2$ have less than $k$ number of nodes. By our induction hypothesis, both $C^1$ and $C^2$ have non-negative length. Hence, the length of the cycle $C$ is non-negative.

\[ \text{Proof of Proposition 1} \]

Proof: Fix a positive integer $K \geq 2$ and an allocation rule $f$. Suppose $f$ is $K$-cycle monotone. To show that $f$ is strong $(K - 1)$-generation monotone, consider any type $t_i$ such that $t_i$ is not satisfied (if no such $t_i$ exists, then we are done vacuously). Pick any $t_i^h \in G^K_f(t_i)$, where $k \leq (K - 1)$. We show that $f$ satisfies GSS, MON, and NR by using induction on $k$.

For $k = 1$, consider the 2-cycle $(t_i, t_i^h, t_i)$. The length of the edge from $t_i^h$ to $t_i$ is $-v(t_i)$. Hence, the length of the edge from $t_i$ to $t_i^h$ is at least $v(t_i)$. But the length of the edge from $t_i$ to $t_i^1$ is

$$v(t_i^1)[\delta(f(t_i^1), t_i^1) - \delta(f(t_i), t_i^1)].$$

This length is at least $v(t_i)$ only if $\delta(f(t_i^1), t_i^1) = 1$ (GSS), $\delta(f(t_i), t_i^1) = 0$ (NR), and $v(t_i^1) \geq v(t_i)$ (MON).

Now, assume that $f$ satisfies GSS, MON, and NR for all $k < r \leq (K - 1)$. We will show that for any $t_i^r \in G^K_f(t_i)$, we have $t_i^r$ is satisfied, $v(t_i^r) \geq v(t_i)$, and $t_i$ does not satisfy $t_i^r$. We pick $t_i^1, t_i^2, \ldots, t_i^{r-1}$ such that $t_i^j \in G^K_f(t_i)$ for all $j \in \{1, \ldots, r - 1\}$ and $\delta(f(t_i^j), t_i^{j-1}) = 1$ for all $j \in \{1, \ldots, r - 1\}$, where $t_i^0 = t_i$. By our induction hypothesis, $\delta(f(t_i^j), t_i^j) = 1$ (GSS) for all $j \in \{1, \ldots, r - 1\}$. As a result, for any $j \in \{2, \ldots, r\}$, the length of the edge $(t_i^j, t_i^{j-1})$ is zero. So, the length of the cycle $C \equiv (t_i, t_i^r, t_i^{r-1}, \ldots, t_i^1, t_i)$ is

$$v(t_i^r)[\delta(f(t_i^r), t_i^r) - \delta(f(t_i), t_i^r)] + v(t_i)[\delta(f(t_i), t_i) - \delta(f(t_i^1), t_i)].$$

By our assumption $\delta(f(t_i^1), t_i) = 1$ and $\delta(f(t_i), t_i) = 0$. Hence, the length of the cycle $C$ is

$$v(t_i^r)[\delta(f(t_i^r), t_i^r) - \delta(f(t_i), t_i^r)] - v(t_i).$$

By our assumption the length of the cycle $C$ is non-negative. This can be made non-negative only if $v(t_i^r) \geq v(t_i)$ (MON), $\delta(f(t_i^r), t_i^r) = 1$ (GSS), and $\delta(f(t_i), t_i^r) = 0$ (NR). This concludes the proof that $f$ is strong $(K - 1)$-generation monotone.

Now, for the converse, suppose $f$ is strong $(K - 1)$-generation monotone. We show that $f$ is $K$-cycle monotone. We use induction on $K$. We do the proof in several steps. Step 1
establishes the base case \((K = 2)\) of induction, while various sub-steps of Step 2 proves the inductive step.

**Step 1:** Consider \(K = 2\). We show that \(f\) is 2-cycle monotone. Consider a cycle \((s_i, t_i, s_i)\), and assume for contradiction that it has negative length. Then, at least one of the edges in the cycle has negative length. Without loss of generality, let the length of edge from \(s_i\) to \(t_i\) be negative. Then, \(v(t_i)[\delta(f(t_i), t_i) - \delta(f(s_i), t_i)] = -v(t_i) < 0\). This implies that \(\delta(f(t_i), t_i) = 0\) but \(\delta(f(s_i), t_i) = 1\). Hence, \(t_i\) is not satisfied but \(s_i \in G_1^f(t_i)\). By strong generation monotonicity, \(s_i\) is satisfied, \(v(s_i) \geq v(t_i)\), and \(s_i\) is not satisfied by \(t_i\). This implies that the length of the edge \((t_i, s_i)\) is \(v(s_i) \geq v(t_i)\). Hence, the length of the 2-cycle is non-negative, which is a contradiction.

**Step 2:** Consider \(K > 2\). Suppose \(f\) is \(k\)-cycle monotone for all \(k < K\). We show that \(f\) is \(K\)-cycle monotone. We do the proof in several sub-steps.

**Step 2A:** We consider any cycle \(C \equiv (t_i^1, \ldots, t_i^K, t_i^1)\), such that \(t_i^j\) is satisfied for all \(j \in \{1, \ldots, K\}\). In that case, the length of any arbitrary edge \((t_i^j, t_i^{j+1})\) of this cycle is \(v(t_i^{j+1})[\delta(f(t_i^{j+1}), t_i^{j+1}) - \delta(f(t_i^j), t_i^{j+1})] \geq 0\), where we denote \((j + 1) \equiv 1\) if \(j = K\). Hence, the cycle \(C\) has non-negative length.

**Step 2B:** We consider any cycle with \(K\) nodes where exactly one node, say \(t_i\), is not satisfied and all other nodes are satisfied. Denote this cycle by \(C \equiv (t_i, t_i^{K-1}, t_i^{K-2}, \ldots, t_i^1, t_i)\). Note that the length of any edge \((t_i^j, t_i^{j-1})\) for any \(j \in \{2, \ldots, K\}\), where \(t_i^K \equiv t_i\), is equal to

\[
v(t_i^{j-1})[\delta(f(t_i^{j-1}), t_i^{j-1}) - \delta(f(t_i^j), t_i^{j-1})] = v(t_i^{j-1})[1 - \delta(f(t_i^j), t_i^{j-1})],
\]

which is equal to \(v(t_i^{j-1})\) if \(t_i^{j-1}\) is not satisfied by \(t_i^j\) and equal to zero if \(t_i^{j-1}\) is satisfied by \(t_i^j\). Thus, all such edges have non-negative length.

Now, consider the edge \((t_i^1, t_i)\). The length of this edge is

\[
v(t_i)[\delta(f(t_i), t_i) - \delta(f(t_i^1), t_i)] = -v(t_i)\delta(f(t_i^1), t_i).
\]

If \(\delta(f(t_i^1), t_i) = 0\), then the length of the cycle \(C\) is non-negative. Else, the length of the edge \((t_i^1, t_i)\) is \(-v(t_i)\), and it is the only negative length edge of \(C\). In this case, \(t_i^1 \in G_1^f(t_i)\). By \(\text{MON}\), \(v(t_i^1) \geq v(t_i)\). Now, we evaluate the length of edge \((t_i^2, t_i^1)\). If \(\delta(f(t_i^2), t_i^1) = 0\) then the length of the edge \((t_i^2, t_i^1)\) is \(v(t_i^1) \geq v(t_i)\), and hence, the length of the cycle \(C\) is non-negative. Else, \(\delta(f(t_i^2), t_i^1) = 1\) implies that \(t_i^2 \in G_2^f(t_i)\). By generation monotonicity, \(v(t_i^2) \geq v(t_i)\). Continuing in this manner, we will either find a node/type \(t_i^j\), where \(j \in \{2, \ldots, K - 1\}\), such that \(v(t_i^j) \geq v(t_i)\) and \(\delta(f(t_i^j), t_i^{j-1}) = 0\) or we will reach at edge \((t_i, t_i^{K-1})\) with \(t_i^{K-1} \in G_{K-1}^f(t_i)\). The length of this edge is

\[
v(t_i^{K-1})[\delta(f(t_i^{K-1}), t_i^{K-1}) - \delta(f(t_i), t_i^{K-1})].
\]
By strong \((K-1)\)-generation monotonicity, \(v(t_{i}^{K-1}) \geq v(t_{i})\), \(\delta(f(t_{i}^{K-1}), t_{i}^{K-1}) = 1\), and \(\delta(f(t_{i}), t_{i}^{K-1}) = 0\). Hence, the length of this edge is \(v(t_{i}^{K-1}) \geq v(t_{i})\). This shows that the length of the cycle \(C\) is non-negative.

**Step 2c:** In this step, we show that for any \(s_{i}\) and \(t_{i}\) such that \(s_{i}\) and \(t_{i}\) are not satisfied, the length of the edge \((s_{i}, t_{i})\) is zero. Consider any 2-cycle \(C \equiv (s_{i}, t_{i}, s_{i})\) such that \(s_{i}\) and \(t_{i}\) are not satisfied. The length of \(C\) is zero. To see this, note that the length of \(C\) is non-negative since \(f\) is 2-cycle monotone by our induction hypothesis. Further, the length of \(C\) is

\[
v(t_{i})[\delta(f(t_{i}), t_{i}) - \delta(f(s_{i}), t_{i})] + v(s_{i})[\delta(f(s_{i}), s_{i}) - \delta(f(t_{i}), s_{i})]
\]

\[
= -[v(t_{i})\delta(f(s_{i}), t_{i}) + v(s_{i})\delta(f(t_{i}), s_{i})] \leq 0.
\]

This shows that the length of \(C\) is zero. Hence, the length of the edges from \(s_{i}\) to \(t_{i}\) and from \(t_{i}\) to \(s_{i}\) are both zero. This shows that in any cycle where all the nodes are not satisfied, the length of the edges in this cycle must be zero.

**Step 2d:** Now, we will show that the length of a particular cycle is non-negative. A cycle \((t_{1}, \ldots, t_{h}^{h}, t_{1}^{l})\) is an **interior cycle** if \(h \geq 3\), \(t_{1}^{h}\) and \(t_{h}^{h}\) are not satisfied and \(t_{i}^{l}\) is satisfied for all \(j \in \{2, \ldots, h-1\}\). Consider an interior cycle \(C \equiv (t_{1}^{l}, \ldots, t_{K}^{l}, t_{1}^{l})\) with \(K > 2\). We will show that its length is non-negative. Since \(C\) is an interior cycle, assume without loss of generality that \(t_{1}^{l}\) and \(t_{K}^{l}\) are not satisfied, but \(t_{i}^{l}\) is satisfied for all \(j \in \{2, \ldots, K-1\}\). Since \(f\) is 2-cycle monotone (by our induction hypothesis), the length of edge \((t_{i}^{K-1}, t_{i}^{l})\) is zero - this follows from Step 2c. The length of the edge \((t_{i}^{K-1}, t_{i}^{l})\)

\[
v(t_{i}^{K})[\delta(f(t_{i}^{K}), t_{i}^{l}) - \delta(f(t_{i}^{K-1}), t_{i}^{l})].
\]

Since \(\delta(f(t_{i}^{K}), t_{i}^{l}) = 0\), the length of the edge \((t_{i}^{K-1}, t_{i}^{l})\) is non-positive. Now, consider any edge \((t_{i}^{l}, t_{i}^{l+1})\) in cycle \(C\) such that \((t_{i}^{l}, t_{i}^{l+1}) \notin \{(t_{i}^{K-1}, t_{i}^{l}), (t_{i}^{K}, t_{i}^{l})\}\), where \((j+1) \equiv 1\) if \(j = K\). By definition, \(\delta(f(t_{i}^{l+1}), t_{i}^{l+1}) = 1\). Hence, length of this edge is non-negative.

Hence, the only edge in \(C\) which may have a negative length is \((t_{i}^{K-1}, t_{i}^{l})\). Suppose the length of edge \((t_{i}^{K-1}, t_{i}^{l})\) is negative. In that case, \(\delta(f(t_{i}^{K-1}), t_{i}^{l}) = 1\), and the length of the edge is \(-v(t_{i}^{l})\). We will show that some other edge in \(C\) has a length greater than or equal to \(v(t_{i}^{l})\).

Note that \(t_{i}^{K-1} \in G_{1}^{l}(t_{i}^{K})\). By strong generation monotonicity, \(v(t_{i}^{K-1}) \geq v(t_{i}^{l})\). The length of the edge \((t_{i}^{K-2}, t_{i}^{K-1})\) is either zero or \(v(t_{i}^{K-1})\). If it is \(v(t_{i}^{K-1})\), we are done. Else, \(\delta(f(t_{i}^{K-2}), t_{i}^{K-1}) = 1\) implies that \(t_{i}^{K-2} \in G_{2}^{l}(t_{i}^{K})\). By strong generation monotonicity again, \(v(t_{i}^{K-2}) \geq v(t_{i}^{K})\). Continuing in this manner, we will either find an edge whose length is greater than or equal to \(v(t_{i}^{l})\) or reach the edge \((t_{1}^{l}, t_{1}^{l})\) with zero edge length, and \(t_{1}^{l} \in G_{K-1}^{l}(t_{1}^{l})\). In that case, strong \((K-1)\)-generation monotonicity will imply that \(\delta(f(t_{1}^{l}), t_{1}^{l}) = 1\), which is a contradiction.
**Step 2E:** In the final step, we will consider a cycle with \( K \) nodes, where \( K > 2 \). By Steps 2B-2D, we need to consider only the case where \( C \) has at least two nodes not satisfied, and \( C \) is not an interior cycle. In that case, we find a node, say \( t_i^1 \), such that \( t_i^1 \) is not satisfied but \( t_i^2 \) is satisfied. Note that if no such node exists, then either \( C \) is an interior cycle or all nodes are not satisfied, which is not possible by the definition of \( C \).

Now, starting from \( t_i^1 \), we go along the cycle \( C \), and let \( t_i^j \) be the next node which is not satisfied by \( f \). By construction \( 2 < j < K \). We break \( C \) into two cycles \( C^1 \) and \( C^2 \), where \( C^1 = (t_i^1, \ldots, t_i^j, t_i^1) \) and \( C^2 = (t_i^j, t_i^{j+1}, \ldots, t_i^K, t_i^1) \). Note that the total length of \( C^1 \) and \( C^2 \) is the total length of \( C \) and the length of the 2-cycle \((t_i^j, t_i^1, t_i^j)\). But by Step 2c, the 2-cycle \((t_i^j, t_i^1, t_i^j)\) has zero length. Hence, the length of \( C \) and the total length of \( C^1 \) and \( C^2 \) are equal. Note that \( C^1 \) and \( C^2 \) have less than \( K \) nodes. By our induction hypothesis, the total length of \( C^1 \) and \( C^2 \) is non-negative. Hence, the length of \( C \) is non-negative. This concludes the proof. \( \square \)

**Proof of Theorem 4**

**Proof:** We use a result in Heydenreich et al. (2009) to prove our theorem. We say that an implementable allocation rule \( f \) satisfies revenue equivalence if for any two payment rules \( p_i \) and \( p_i' \) there exists a constant \( c_i \) such that for all \( s_i \), \( p_i(s_i) = p_i'(s_i) + c_i \). Heydenreich et al. (2009) characterize allocation rules which satisfy revenue equivalence. To describe and use their result, we need the following notations.

Consider the type graph corresponding to rich dichotomous domain \( \mathcal{D}_i \) and allocation rule \( f \). For any pair of types \( s_i \) and \( t_i \), a path in the type graph from \( s_i \) to \( t_i \) is a sequence of distinct nodes \( P = (s_i, s_i^1, \ldots, s_i^k, t_i) \). Denote by \( l(P) \) the length of a path \( P \). Let \( P_{s_i, t_i} \) be the set of all paths from \( s_i \) to \( t_i \). Define \( \text{dist}^f(s_i, t_i) := \inf_{P \in P_{s_i, t_i}} l(P) \), i.e., the length of the shortest path from \( s_i \) to \( t_i \) in the type graph. If \( f \) is implementable then it can be shown that for all \( s_i, t_i \in \mathcal{D}_i \), \( \text{dist}^f(s_i, t_i) \) is a real number and \( \text{dist}^f(s_i, t_i) + \text{dist}^f(t_i, s_i) \geq 0 \) (Heydenreich et al., 2009).

Heydenreich et al. (2009) show that an allocation rule \( f \) satisfies revenue equivalence if and only if for all \( s_i, t_i \in \mathcal{D}_i \), we have \( \text{dist}^f(s_i, t_i) + \text{dist}^f(t_i, s_i) = 0 \). We show that this condition holds in our domain. Consider two dichotomous types \( s_i, t_i \in \mathcal{D}_i \). Assume for contradiction, \( \text{dist}^f(s_i, t_i) + \text{dist}^f(t_i, s_i) = \epsilon > 0 \). Consider two types \( \bar{s}_i \) and \( \bar{t}_i \) such that \( A(\bar{s}_i) = A(s_i), A(\bar{t}_i) = A(t_i), v(\bar{s}_i) < v(s_i), v(\bar{t}_i) < v(t_i) \), and \( v(\bar{s}_i) + v(\bar{t}_i) < \epsilon \). Note that because of this

\[
\ell(\bar{s}_i, \bar{t}_i) + \ell(\bar{t}_i, \bar{s}_i) < \epsilon.
\]

We now look at the shortest paths between \( s_i \) and \( \bar{s}_i \). Note that \( s_i \) and \( \bar{s}_i \) have the same acceptable set. If \( \delta(f(s_i), s_i) = \delta(f(\bar{s}_i), \bar{s}_i) \), then \( \ell(s_i, \bar{s}_i) + \ell(\bar{s}_i, s_i) = 0 \), and hence, \( \text{dist}^f(s_i, \bar{s}_i) + \text{dist}^f(\bar{s}_i, s_i) = 0 \). Else, since \( v(\bar{s}_i) < v(s_i) \), by Theorem 3, \( \delta(f(s_i), s_i) = 1 \) and \( \delta(f(\bar{s}_i), \bar{s}_i) = 0 \). Let the cutoff corresponding to \( A(s_i) \) be \( C(A(s_i)) \). Then, we have
We consider two cases.

**Case 1:** Suppose \( f(s'_i) \in A(s_i) \). Then, \( v(\bar{s}_i) < C(A(s_i)) \). Choose another type \( s''_i \) such that \( A(s''_i) = A(s_i) \) and \( v(s''_i) = v(s'_i) - \epsilon' > v(\bar{s}_i) \). The 2-cycle between \( s_i \) and \( s'_i \) has length zero since \( A(s_i) = A(s'_i) \) and \( \delta(f(s_i), s_i) = \delta(f(s'_i), s'_i) = 1 \). Further, the 2-cycle between \( s''_i \) and \( \bar{s}_i \) has length zero since \( A(s_i) = A(s''_i) \) and \( \delta(f(s''_i), s''_i) = \delta(f(\bar{s}_i), \bar{s}_i) = 0 \). Finally, the 2-cycle between \( s'_i \) and \( s''_i \) has a length equal to

\[
 v(s'_i)[\delta(f(s'_i), s'_i) - \delta(f(s''_i), s'_i)] + v(s''_i)[\delta(f(s''_i), s''_i) - \delta(f(s'_i), s''_i)] = v(s'_i) - v(s''_i) = \epsilon'.
\]

Hence, sum of lengths of the path \((s_i, s'_i, s''_i, \bar{s}_i)\) and the path \((\bar{s}_i, s''_i, s'_i, s_i)\) is \( \epsilon' \).

**Case 2:** Suppose \( f(s'_i) \notin A(s_i) \). Then \( v(s_i) > C(A(s_i)) \), and we can choose \( s''_i \) to be a type such that \( A(s''_i) = A(s_i) \) and \( v(s''_i) = v(s'_i) + \epsilon' < v(s_i) \). Using a similar argument to Case 1, we can show that the length of the 2-cycle between \( s'_i \) and \( s''_i \) is \( \epsilon' \). Further, the 2-cycles between \( s_i \) and \( s''_i \) and between \( s'_i \) and \( \bar{s}_i \) is zero. Hence, sum of lengths of the path \((s_i, s''_i, s'_i, \bar{s}_i)\) and the path \((\bar{s}_i, s''_i, s'_i, s_i)\) is \( \epsilon' \).

So, we conclude that \( dist^f(s_i, \bar{s}_i) + dist^f(\bar{s}_i, s_i) \leq \epsilon' \). Since \( \epsilon' \) can be chosen arbitrarily close to zero, we conclude that \( dist^f(s_i, \bar{s}_i) + dist^f(\bar{s}_i, s_i) = 0 \). Because of this, there is a path \( P \) from \( s_i \) to \( \bar{s}_i \) and another path \( P' \) from \( s'_i \) to \( s_i \) such that \( l(P) + l(P') \) is arbitrarily close to zero.

Using a similar argument, we can show that \( dist^f(t_i, \bar{t}_i) + dist^f(\bar{t}_i, t_i) = 0 \). Because of this, there is a path \( Q \) from \( t_i \) to \( \bar{t}_i \) and another path \( Q' \) from \( \bar{t}_i \) to \( t_i \) such that \( l(Q) + l(Q') \) is arbitrarily close to zero.

Hence, the total length of \( l(P) + l(\bar{t}_i, \bar{t}_i) + l(Q') + l(Q) + l(\bar{t}_i, \bar{s}_i) + l(P') < \epsilon \). This is a contradiction to the fact that \( dist^f(s_i, t_i) + dist^f(t_i, s_i) = \epsilon \). The proof is now concluded by observing from Proposition 2 that one payment rule \( p^* \) which implements \( f \) is \( p_i^*(t_i) = \kappa_i^f(f(t_i)) \delta(f(t_i), t_i) \) for all \( t_i \).

**APPENDIX 2: APPLICATIONS TO SPECIFIC DICHOTOMOUS DOMAINS**

In this section, we will look at very specific dichotomous domains and apply our general characterization result of Theorem 1 to these specific domains. We stick to the model of a single agent, denoted by \( i \). We do not require the richness assumption for these domains.

**Unique Dichotomous Domain**

Consider a domain where the dichotomous type always has a single element in the acceptable set. For example, in the scheduling problem discussed in Section 1, the task is available only
for one period. We call such a dichotomous type, a unique dichotomous type. A domain \( D_i \) is called a unique dichotomous domain if each type \( t_i \in D_i \) is a unique dichotomous type. Formally, a unique dichotomous type \( t_i \in D_i \) satisfies \( |A(t_i)| = 1 \). An implication of Theorem 1 is that 1-generation monotonicity (equivalently 2-cycle monotonicity) is necessary and sufficient for implementability in unique dichotomous domain.

**Theorem 6** Suppose \( f : D_i \to A \), where \( D_i \) is a unique dichotomous domain. Then, \( f \) is implementable if and only if it is 2-cycle monotone.

*Proof:* Consider any allocation rule \( f : D_i \to A \), where \( D_i \) is a unique dichotomous domain. We already know that implementability implies 2-cycle monotonicity. Now, suppose \( f \) is 2-cycle monotone. Then, by Proposition 1, \( f \) is strong 1-generation monotone. We will show that \( \gamma^f = 1 \). Assume for contradiction that \( \gamma^f > 1 \). This means that there is at least one unsatisfied \( t_i \), which is satisfied at some \( s_i \in D_i \), i.e., \( s_i \in G^f_1(t_i) \) and there is some \( \bar{s}_i \in G^f_2(t_i) \) such that \( s_i \) is satisfied at \( \bar{s}_i \). By 1-generation monotonicity, \( s_i \) must satisfy itself. So, \( A(s_i) = \{ f(s_i) \} \). Since \( t_i \) is satisfied at \( s_i \), it must be that \( A(s_i) = A(t_i) = \{ f(s_i) \} \). But \( A(s_i) = \{ f(\bar{s}_i) \} \). This implies that \( A(t_i) = \{ f(\bar{s}_i) \} \). This means that \( \bar{s}_i \in G^f_1(t_i) \), which is a contradiction.

As a consequence of this, strong 1-generation monotonicity implies strong \( K \)-generation monotonicity, for all positive integer \( K \). But this implies implementability by Theorem 1. ■

**Remark.** A unique dichotomous domain is not convex in \( \mathbb{R}^{|A|} \). But Theorem 6 shows that 2-cycle monotonicity is necessary and sufficient for implementability in this domain. This result does not contradict Ashlagi et al. (2010), who give a characterization of domains where 2-cycle monotonicity is equivalent to randomized and finite-valued implementability.

**Unit Demand Dichotomous Domain**

We now study another specific dichotomous domain. Here the set of alternatives is constructed from a ground set. Suppose \( M \) is a finite set of objects, and let \( |M| = m \geq 2 \). The set of alternatives is the set of all non-empty subsets of objects: \( A = \{ S \subseteq M : S \neq \emptyset \} \). The favorite set of the agent at any type \( t_i \) is described by a subset of objects, denoted by \( F(t_i) \subseteq M \). The interpretation of \( F(t_i) \) is that if the agent gets any object from \( F(t_i) \) then he gets a value of \( v(t_i) \), else he gets a value of zero. So, the acceptable set of the agent is \( A(t_i) = \{ S \in A : F(t_i) \cap S \neq \emptyset \} \). Any domain \( D_i \) in which every type \( t_i \in D_i \) is characterized by such favorite objects is called a unit demand dichotomous domain. Note that a unit demand dichotomous domain is not a rich domain.

There are collective choice problems where unit demand dichotomous domain is plausible. Consider the problem of a firm which wants to hire a group of consultants for giving training to employees in different departments. Each consultant has different expertise, and can give
training in a specific area. Each department in the firm has a specific training requirement. So, every department has a favorite set of consultants, and that determines its acceptable sets.

We can use our general result in Theorem 1 to derive a precise characterization of implementability in such domains.

**Theorem 7** Suppose $f : \mathcal{D}_i \to \mathcal{A}$ is an allocation rule, where $\mathcal{D}_i$ is a unit demand dichotomous domain. Then, $f$ is implementable if and only if it is $m$-cycle monotone if and only if it is $(m-1)$-generation monotone.

**Proof:** Consider an allocation rule $f : \mathcal{D}_i \to \mathcal{A}$, where $\mathcal{D}_i$ is a unit demand dichotomous domain. It is well known that if $f$ is implementable then it is cycle monotone, and hence, $m$-cycle monotone. For the converse, suppose $f$ is $m$-cycle monotone. By Proposition 1, $f$ is strong $(m-1)$-generation monotone. We will show that $\gamma_f \leq (m-1)$, and hence, $f$ is then strong $\gamma_f$-generation monotone. Using Theorem 1, we can then conclude that $f$ is implementable.

Assume for contradiction that $\gamma_f > (m-1)$. Then, there must exist a type $t_i \in \mathcal{D}_i$ such that for every integer $k \leq m$, there exists $t^k_i \in G^f_k(t_i)$. For simplicity of notation, denote $t_i$ as $t^0_i$, and for all $k \in \{0, \ldots, m\}$, denote $F(t^k_i)$ as $F^k$ and $f(t^k_i)$ as $T^k$.

We will first show that for every $k \in \{0, \ldots, m-1\}$, $|\bigcup_{j=0}^{K-1} F^j \cup T^0| \geq (k + 2)$. Since $t_i$ does not satisfy itself, $|F^0 \cup T^0| \geq 2$. Hence, the claim is true for $k = 0$. Now, we will use induction. Suppose the claim is true for all $k < K$, where $(m-1) \geq K > 0$, and we show that it holds for $k = K$. By definition, $t^{K+1}_i \in G^f_{K+1}(t_i)$ exists. Further, $T^{K+1} \cap F^j = \emptyset$ for all $j \in \{0,1,\ldots,K-1\}$. Hence, $T^{K+1} \subseteq (M \setminus \bigcup_{j=0}^{K-1} F^j)$. Since $T^{K+1} \cap F^K \neq \emptyset$, we get that $F^K$ contains at least one object which is not present in $\bigcup_{j=0}^{K-1} F^j$. By strong $(m-1)$-generation monotonicity, $T^0 \cap F^j = \emptyset$ for all $j \in \{0,1,\ldots,K\}$. Hence, $F^K$ contains at least one object which is not present in $\bigcup_{j=0}^{K-1} F^j \cup T^0$. Using our induction hypothesis, we know that $|\bigcup_{j=0}^{K-1} F^j \cup T^0| \geq (K + 1)$. Hence, $|\bigcup_{j=0}^{K-1} F^j \cup T^0| \geq (K + 2)$. But this implies that $|\bigcup_{j=0}^{m-1} F^{m-1} \cup T^0| \geq (m + 1)$. This is a contradiction since the number of objects is $m$.

Since the number of generations is $(m-1)$, strong $(m-1)$-generation monotonicity is equivalent to $(m-1)$-generation monotonicity.

**Single-Minded Domain**

Single-minded domain is a particular dichotomous domain. Like unit demand dichotomous domain, a ground set $M$ is given, say a set of objects. The set of alternatives is all subsets of $M$, i.e., $\mathcal{A} = \{S : S \subseteq M\}$ - note that the empty set can also be an alternative, which is worthless. A domain $\mathcal{D}_i$ is single minded if for every dichotomous type $t_i \in \mathcal{D}_i$, there exists a non-empty set of objects $M(t_i) \subseteq M$ such that $\mathcal{A}(t_i) = \{S \in \mathcal{A} : M(t_i) \subseteq S\}$. A type in the single-minded domain will be referred to as a single-minded type. Given a type,
$t_i \equiv (A(t_i), v(t_i))$, the bundle of objects $M(t_i)$ is called the **favorite** bundle of objects and $v(t_i)$ is the value of any bundle of objects containing $M(t_i)$.

It is well-known that the 2-cycle monotonicity does not imply implementability in single-minded domains (Babaioff et al., 2005). First we examine this domain with some restrictions on the allocation rules.

**Definition 11** An allocation rule $f : D_i \rightarrow A$, where $D_i$ is a single-minded domain, is **weakly exact** if for every single-minded type $t_i \in D_i$, $f(t_i) \subseteq M(t_i)$. Allocation rule $f$ is **exact** if for every single-minded type $t_i \in D_i$, $f(t_i) \in \{\emptyset, M(t_i)\}$.

We now show that the generation number of implementable weakly exact allocation rule is one.

**Theorem 8** Suppose $f : D_i \rightarrow A$ is a weakly exact allocation rule, where $D_i$ is a single-minded domain. Then, $f$ is implementable if and only if it is 2-cycle monotone.

**Proof:** Implementability implies cycle monotonicity, and hence, 2-cycle monotonicity. Suppose $f$ is weakly exact and satisfies 2-cycle monotonicity. By Proposition 1, $f$ is strong 1-generation monotone. We will show that $\gamma^f = 1$, and by Theorem 1, $f$ is implementable. Assume for contradiction that $\gamma^f > 1$. Then, there exists a single minded type $t_i \in D_i$ and $t_1^i \in G_1^f(t_i)$ and $t_2^i \in G_2^f(t_i)$. By GSS and weak exactness, $M(t_1^i) = f(t_1^i)$. Also, by definition, $M(t_i) \subseteq f(t_1^i)$, and hence, $M(t_i) \subseteq M(t_1^i)$. By GSS and weak exactness, $M(t_2^i) = f(t_2^i)$, and $M(t_1^i) \subseteq f(t_2^i)$. But this implies that $M(t_i) \subseteq f(t_2^i)$. This means that $t_2^i \in G_1^f(t_i)$, which is a contradiction. ■

As a corollary, we recover a well known result for single-minded domains.

**Corollary 2 (Lehmann et al. (2002))** Suppose $f : D_i \rightarrow A$ is an exact allocation rule, where $D_i$ is a single-minded domain. Then, $f$ is implementable if and only if it is 2-cycle monotone.

**Remark.** Weak exactness may be more appealing than exactness in some settings. Consider a seller who is faced with many buyers (more than the number of objects). Suppose the seller never wants to retain any object - may be due to high inventory costs. In that case, an exact allocation rule will not allocate all the objects in some instances, but a weakly exact allocation rule will allocate all the objects if the number of buyers is more than the number of objects.

These results show that if we restrict the class of allocation rules in single-minded domains in a certain way, then the generation number of single-minded domain is one.

**Remark.** In general, it is possible to determine the generation number of a single-minded domain without any restriction on the allocation rules. Unfortunately, it turns out that the generation number of single-minded domain is an exponential function of $m$. A formal proof of this fact is available upon request. We omit the result here since we already know that the generation number in any domain is bounded above by $|A| = 2^m$, and our finding does not simplify this characterization significantly.
